widely even within single societies, this sector is extremely heterogeneous. Third, there is agreement among researchers working on the informal economy that the sector has grown in size in many different social and economic contexts in the past few decades. Brisk population growth, increasing landlessness, inadequate social support programs, and growing rural-urban migration are presumably some of the factors that have ensured that large enterprises are unable to create enough jobs to absorb the swelling supply of labor. Under such circumstances, increasing numbers of urban and rural people have been forced to, or have chosen to, create alternative sources of employment. All such unregistered, and therefore unrecognized, manufacturing, service, and petty trade activities are also collectively known as the informal sector—the sector of economic activity that is not registered with government agencies and does not comply with regulations governing labor practices, taxes, and licensing. In India, for example, the informal sector is estimated to account for 93% of the total labor force and 64% of the gross domestic product.

Because it is inaccurate and unjust to describe such a large dynamic workforce in terms that relegate it to a peripheral position, many authors and activists prefer to use the term *self-employed*, arguing that these workers are essentially entrepreneurs since they assume all the risks of their businesses. The term *self-employed* seems appropriate to describe people who attempt to generate independent livelihoods under a variety of circumstances, compared with other terms with pejorative connotations, such as *casual* work, or illegal connotations, such as *black economy*, derived from the Italian *lavoro negro*, traditionally used to describe people with connections to the mafia, or *marginal* economy, which utterly fails to capture the significant economic contributions of the sector. The concern some researchers express about the use of the term *self-employed* arises from the possible confusion of the meaning attributed to it by Western capitalism. Self-employment in the context of the industrialized world may imply informed choice to pursue independent livelihoods in the presence of other opportunities. An overwhelming number of people in the developing world as well as some vulnerable groups such as undocumented workers in developed countries are driven to the informal sector not out of a desire to be entrepreneurial but because of lack of options and unmet household subsistence requirements. The absence of a fixed employer, or the difficulty of identifying one due to elaborate chains of subcontracting, is a common characteristic of this sector and one that ensures that workers remain in precarious casual, contractual, migrant, or home-based work environments. While flexibility in working hours and in locations of work is perceived as an attractive option in the formal sector, for socially vulnerable groups it usually translates into undesirable working conditions. Home-based informal-sector workers, for example, frequently work longer and harder hours than formal-sector workers but fail to avail themselves of any legal entitlements for minimum wages or social security benefits, sometimes despite the existence of protective legislation. Hidden but effective structures of dependency make it difficult to supply the evidence needed to prove that the real nature of the relationship between many of the informal-sector workers and those who pay for their work is one of employees and employers.

The informal economy simultaneously encompasses many contradictions within different geographical and cultural contexts: flexibility and exploitation; productivity and abuse; aggressive entrepreneurs and vulnerable workers; survival and greed. However, it shares three commonalities. First, research on the informal economy demonstrates its systemic connection with the formal economy. Home-based workers in Indian slums who sew Gap and Eddie Bauer shirt labels for local contractors and undocumented workers who work in meat-packing plants in the United States demonstrate that the informal sector is an integral component of national and global economies and not a marginal appendix to them. Second, informal-sector workers tend to receive fewer benefits and lower wages and experience worse working conditions than formal-sector workers. This is a prerequisite for their entry into the labor market. Third, although informal workers are frequently harassed, governments tend to tolerate and even stimulate informal economic activities in order to promote political patronage or resolve social conflict. This is as true in governmental attitudes toward “illegals” in North America or Europe as it is in the experiences of squatter settlements in the burgeoning cities of the global South.

INFORMATION SOCIETY

Today, more people are exposed and have access to more information than anytime in the past. This situation results from the information economy. Easy access and ample exposure to information has reshaped modern societies, permeated everyday life, and now influences the decisions people make and the opportunities they seek. There are even world summits that solely address the issues of an information society. Yet not everyone has equal access to information, and geographic patterns of information access have emerged. In effect, areas of higher economic development typically have greater exposure and access to information than lagging areas. This trend is true at the global, national, or regional scale. Some regions and urban places are tied to the information network to a greater extent than others, and such places tend to be sources for information.

The growth of an information society is tied heavily to information and communication technologies. The introduction of the telegraph helped collapse space in the 19th century. Ensuing developments in radio and phone technology furthered the collapse. Television has profoundly affected our ability to access information even to the point of it influencing how we might vote. Today, the Internet is one of the more viable avenues for accessing information. As information technology escalates in ingenuity and capacity, so does the ability of societies to effectively handle information and information flows. The Internet has become a popular way for businesses and institutions to interact with one another, for people to find information pertinent to their needs, or for converting information in hardcopy to a digital format. As such, modern societies have entered the digital age of information.

Not all societies have equal access to digital information. Those that are not fully enveloped within the information network typically have smaller national outputs, or fewer computers, televisions, and phones per person. Still, the ability to access information on the Internet and television or by phone has never been easier anywhere. The economic benefits that can accrue from information flows have for the most part reinforced

existing spatial economic patterns. The Internet has not significantly reshaped spatial economies; if anything it has reinforced their structure. Those regions that are notably tied to a nodal center for economic leadership will continue to be so in the information age. As such, one might view information societies as hierarchically organized, with some people and regions having greater access to tacit information and being further up the hierarchy. Because of this hierarchical structure, it is not practical to view global information patterns as wholly ubiquitous.

Information patterns can be broken into different layers: that which is explicit (or easy to understand and open to public use); that which is tacit (or strategic and difficult to attain); and those layers in between, of which each will produce different geographic patterns. Explicit information patterns or flows will be much more ubiquitous over space than tacit information patterns. It is the concentration of strategic information that has led to truncation in spatial economies. Within information societies, selected cities have subsequently emerged as growth nodes.

Using Internet domains as a proxy for the development of information societies, it becomes clear that some countries and regions dominate. For example, around 45% of domains worldwide recently originated in the United States, and nearly 70% of all domains originate in one of seven countries. While the share of U.S. domains is decreasing, the top seven countries continue to hold around 70%. It is anticipated that as more countries adopt information technology and initiatives, the concentration and control of information patterns could widen. To what extent this happens will unfold in the next few decades.

Though information patterns are becoming somewhat diffuse geographically, it is difficult to parse out quality or tacit information from routine or background information. In the 1930s, Fritz Machlup and Joseph Schumpeter were among the first social scientists to examine patents as a source of knowledge and its distribution. The advantage of using measures of technology as a surrogate for tacit information is that one can isolate highly prized or guarded information. Furthermore, the location of patents can provide an accurate understanding of where key nodes of information exist.

The concept of information society has been compared with the knowledge economy, networked societies, postindustrialism, or the information revolution, to name a few. A commonality in these concepts is that modern societies are becoming increasingly dependent on information, information technologies, and information services. As societies transition from primary to secondary, to postindustrial societies, they inevitably acquiesce to an information society. In fact, the Organisation of Economic Co-operation and Development (OECD) measures the information economy based on the share of a country's GDP (gross domestic product) that is based in this sector. This is done by measuring the amount of regional output that is not based on tangible or manufactured goods. All information societies place a higher premium on codification, infrastructure, and education. Codification enables regions to better manage information in meaningful and competitive ways to create what could be called managed societies. As societies become more information based, they are more apt to become more scientific, technological, and informed. What facilitates this trend, and at the root of an information society, are computers, phones, and other information and communication devices.

Those regions that adapt to being information based will benefit from their early entrance. Whether they can maintain their lead over other regions is contentious. Value-added information that is tradable creates wealth for regions and a new way of working for people. Knowledge and what people do with it is pertinent to the development of an information society. Those regions that foster creativity among their populations are more apt to benefit from an information economy. Added to this is a mobile, educated workforce that desires to live in advantageous locations. The footloose nature of the information economy enables populations to move to desired locations. Still, skilled labor patterns remain concentrated within the so-called footloose nature of the spatial information economy.

INFRASTRUCTURE

Infrastructures are, and have been historically, the fundamental support network of society. This became apparent as urban populations and their densities rapidly increased during the 19th and 20th centuries. The developing complexity of commodity and information flows evident with globalization has also stressed the critical nature of infrastructure in today's world. Infrastructure is the "hidden hand" behind urban development and nation building, enabling the flow of people and critical resources such as water, energy, waste, information, agricultural produce, and manufactured goods. At the same time, inadequate infrastructure provision, or the failure of infrastructure, generates considerable social disorder. In 2005, this failure was evident in New Orleans in the aftermath of Hurricane Katrina.

The term *infrastructure* was first used to define permanent military facilities, such as dry docks, bases, and airstrips. The meaning of infrastructure was eventually extended to include various other public and private works, including water and sewer networks, treatment plants, transportation systems, health, education, communication and computer networks, power systems,

sport stadiums, and arts centers. There are two distinct infrastructure types, *interurban* and *intra-urban* infrastructures. Interurban infrastructure connects cities into a national network, the national urban system, while *intra-urban* infrastructure connects homes and businesses within an urban center, enabling the functioning of a city as a system.

Despite its importance, infrastructure provision throughout the affluent West has become so normalized that it is generally taken for granted. In part, this status is a reflection of the effectiveness of these complex systems in providing crucial services. As argued by David Perry (1995), when infrastructures “work best, they are noticed least of all” (p. 2). In part, however, the increasing oversight of the importance of infrastructure in sustaining social order and quality of life has been facilitated by an important feature of contemporary infrastructure management, concealing infrastructure.

Maria Kaika and Erik Swyngedouw have argued that while through the early 20th century, infrastructure, and particularly urban infrastructure, maintained an important visual role in the urban landscape, being celebrated as technological advancements of modernization, its role within the urban setting was significantly diminished in the late 20th century. This move toward the invisibility of urban infrastructures has been achieved by closing down infrastructure facilities within cities (such as power plants and pumping stations) and sourcing out power, water, and other services from more distant locations. Greater invisibility of infrastructure has also been achieved by moving infrastructure beneath the city, making the urban underground a rich network of pipes, wires, conduits, and transportation networks. The \$15 billion “Big Dig” in Boston, which took 15 years to construct, provides a recent example. The project involved the construction of 7.8 miles of highway, totaling 161 lane miles, with approximately half of the network built underground.

The Role of Government

In the United States, early links between public infrastructure investment and economic and

political security were recognized by President George Washington and his Treasury Secretary Alexander Hamilton. However, it was not until Thomas Jefferson’s presidency that federal investments in infrastructure first became evident. Much of the early investment was placed on interurban infrastructure, canals, roads, and railways. However, in the mid 19th century, research in Britain by John Snow on water supply and cholera and the work by Edwin Chadwick on sanitation and public health placed a new importance on intra-urban infrastructures. In addition, by the late 19th century, a new emphasis on infrastructures within cities was also facilitated by rapid population growth, and the unprecedented urban densities, which began to be realized in the early industrial centers.

The role of government in the delivery of infrastructure is an important issue in infrastructure provision. Two unique characteristics of public infrastructure are recognized that distinguish these goods from private goods, hence their classification as public goods. Public goods are nonrival in consumption and nonexcludable. Nonrival means that once provided many can use a public good without loss of benefits to others and at minimum extra cost in maintenance. The lighthouse provides a classic example. Once provided, many ships can use the services of a lighthouse, and this use does not reduce the services of the lighthouse to other ships. This condition is very different from that of private goods, where the benefits of consumption are limited to the person consuming (e.g., the benefits of eating an orange are limited to the person consuming the orange, because once it is eaten, there is no orange left). Nonexcludability refers to the difficulty of excluding individuals from using public goods once they are provided. For instance, it is very difficult, or very costly, to exclude ships from using lighthouses. Because of nonrivalness and nonexcludability, private companies have little interest in providing public goods, and unless governments intervene, public goods will be provided at suboptimal levels, generating reductions in quality of life and economic performance.

Government intervention in the provision of infrastructure is also justified because of externalities. One type of externality occurs when the

The I-35 bridge collapse site over the Mississippi River 13 days after the collapse

Source: U.S. Navy photo by Mass Communication Specialist Seaman Joshua Adam Nuzzo.

benefits of providing certain goods to society are greater than those recognized by the individuals consuming these goods. An example is education, which has individual benefits to the person receiving the education, but wider social benefits are evident with a more educated and productive workforce. In selecting investment in schooling, individuals will not account for the external social benefits in their decision making and will tend to select suboptimal levels of education. To encourage more socially optimal choices, government subsidization of education is considered acceptable, lowering education costs to individuals and encouraging more years of schooling.

The recognition of public goods and externalities in the provision of public infrastructure emerged through the early and mid 20th century, largely in response to the disorder and chaos brought on by early capitalism. Improvements in quality of life and social well-being following government intervention in infrastructure delivery—particularly apparent in addressing many of

the stresses experienced by the large and rapidly growing industrial centers—illustrate the effectiveness of public infrastructure provision in simultaneously improving both equity and efficiency within cities.

In the late 20th century, a new philosophy and social movement emerged, neoliberalism, which advocated low taxes and minimal government in social and economic activities as a means of improving economic performance. Becoming politically entrenched in the United States following the election of Ronald Reagan as president in 1980, neoliberalism fundamentally altered the public role in infrastructure provision. Private market values and market incentives in the public realm, along with increased competition, public-private partnerships, and privatization became the new focus of government. The relevance of public goods and externalities in infrastructure provision was increasingly dismissed, with significant scaling back of government in the delivery of infrastructure. However, growing concerns over

infrastructure deterioration within this political environment—most recently evident after the collapse of the I-35W freeway bridge in Minneapolis in August 2007—illustrates the necessity of ongoing funding and maintenance of infrastructures.

In addition, despite the widespread acceptance of neoliberalism, there is no evidence to show that low-taxing, minimal-government cities or regions are the best economic performers. In contrast, business and residential concentrations in cities such as London, Paris, Tokyo, and New York are supported by rich and robust infrastructure networks, such as mass transit systems, road and highway networks, air- and seaports, communication networks, education infrastructure, and arts and cultural facilities. Removing just the subway networks from these cities would significantly limit the capacity of moving large populations, with the resulting congestion making existing residential and business concentrations in these urban centers unmanageable. The extensive public infrastructures within these socially and economically robust cities illustrate the importance of rich and robust infrastructure provision in ensuring quality of life and economic well-being.

INNOVATION, GEOGRAPHY OF

For more than a century, geographers and economists have developed theories on the spatial agglomeration of economic activity in response to three empirical observations:

1. A large portion of world output is produced in a limited number of highly concentrated core regions.
2. Firms in similar or related industries tend to collocate in particular places.
3. Both of these patterns seem sustainable over time.

While this outcome has most often been attributed to agglomeration economies, some scholars have long pointed out that the economic and institutional fabric of some areas promotes innovative behavior that further reinforces this pattern.

The most lasting contribution among the early analysts is the economist Alfred Marshall's "industrial districts." Besides mentioning the external benefits that single-activity or closely related producers derive from sharing the fixed costs of common resources such as specialized

infrastructure and services, skilled labor pools, and specialized suppliers, Marshall emphasized that through colocation and frequent interaction, producers share a common knowledge base. By the middle of the 20th century, however, technological changes and the enhancement of labor and entrepreneurial mobility had led most regional growth and development scholars to conclude that “such local specialization . . . [had] become increasingly rare,” while, in contrast, “external economies on the broader basis of urban size and diversity [had] remained a powerful locational force” (Hoover & Giarratani, 1970, p. 121). This perspective, according to which innovative activities were seen as less relevant for industrial agglomeration, probably explains why, along with the development and/or refinement of analytical (mathematical) tools unsuited to the study of innovation, increasingly mechanistic and static “resources allocation” or “location-scanning” perspectives became dominant among analysts.

These theoretical approaches, however, proved unable to account for the spontaneous and spectacular rise in the 1970s and 1980s of numerous regions, from the Silicon Valley and Boston’s Route 128 (Boston) in the United States to the so-called Third Italy, Emilia-Romagna, whose main characteristics were the spatial clustering of related and highly innovative firms. Scholars in disciplines ranging from geography and political science to sociology, business management, and economics thus began to (re)discover and further develop more qualitative and dynamic concepts and insights to explain how the industrial and social characteristics of a given place (ranging in scale from streets and industrial districts to cities and regions) provide or fail to provide fertile soil for innovative behavior or, in other words, how some areas act as focal points for innovative activities. These contributions emphasized not only that colocation gives related firms greater flexibility and the opportunity to quickly adapt to sudden shifts in market demand but also that some places are better than others at integrating the formal and informal collective processes essential to the production of continual innovation. Despite early and constant criticism that this “spatial interaction literature” features a number of ill-defined and overlapping concepts or frameworks (from

“industrial districts,” “innovative milieu,” and “clusters” to “learning regions,” “regional innovation systems,” and “techno-regions”), its main message has always been twofold: (1) Where prosperity exists, it is regionally based and (2) the sources of this prosperity are to be found in the regions themselves and not in some exogenous factors.

Questions in the Geography of Innovation

Fundamentally, the geography of innovation literature asks two questions:

1. Why are some regions more innovative than others?
2. How does a specific location matter for the continuous upgrading of firm capabilities?

The perspective in the former question is that of the region, whereas the latter proceeds from the firm perspective. The answers most commonly provided revolve around the importance of geographical proximity between actors, which greatly facilitates formal and informal collaborations between firms (be they potential competitors or in a user-producer relationship) and/or between firms and research institutions; the spin-off of new firms; and the transmission of tacit knowledge (through face-to-face interactions and the interfirm mobility of skilled workers). Each factor is now examined in turn.

Local Linkages and Collaboration

Geographical proximity, because of the frequent interactions and long-term contracts or commitments among people that it allows (whether in working environments or in social activities), is said to often play a crucial role in building the trust bonds that are needed to share sensitive information and to develop a successful customer-supplier relationship.

Spin-Off Formation

Entrepreneurship, especially in terms of employees creating new firms in close proximity

to former employers (so-called spin-offs or start-ups), is said to be greatly facilitated in some regional contexts. On the one hand, an entrepreneurial culture in which individuals continually leave their employers to launch new firms provides ample demonstration effect, which further reinforces this tendency. On the other, localized industries provide easy access to specialized labor, inputs, and knowledgeable investors, which further facilitates the launch of innovative firms. Spin-offs also tend to create a local or regional environment where firms and individuals interact more with each other than would otherwise be the case.

Tacit Knowledge

The more specialized and innovative an activity is, the more it is likely to be geographically concentrated. The more standardized it becomes, the more it tends to migrate toward customers or inputs. This pattern can be attributed in part to the fact that the crucial knowledge in any innovative industry is not standardized information, routine patterns, or the public knowledge of science but rather what is new, what are the latest changes, and the specialized know-how that individuals have acquired through practice and mistakes. Thus, knowledge from which innovations stem is not freely available, which in turn provides firms that locate near its sources a competitive advantage. As such, globalization and improvements in telecommunication technologies have not crowded out the need for proximity but have conversely strengthened it in cases where crucial knowledge is only locally available. In short, geographical proximity between related firms is said to increase the concentration of knowledge spillovers and the speed of information flows. Even though most of the suppliers and customers of a firm might be located outside its regional setting, being located in a specific area typically allows creative and entrepreneurial individuals to absorb thinking processes, along with specialized vocabulary and ways of doing things, while increasing the probability of useful informal encounter. It also makes it easier for entrepreneurs, managers, and technicians to avoid being caught off guard by unanticipated breakthroughs

by allowing them to monitor emerging technologies closely and to find answers to their questions more rapidly.

While the case on behalf of the geographical base of innovation is strong, it should perhaps be handled more cautiously than it often is for reasons ranging from the fuzziness of the main concepts used in this literature, the continued importance of both traditional agglomeration economies and nonregional networks and linkages, and the fact that individuals were born in or like a particular location.

INPUT-OUTPUT MODELS

Developed by Wassily Leontief in 1936, input-output models are an alternative to simple economic base and Keynesian approaches to modeling an economic system. Essentially, the models are used to describe and analyze forward and

backward economic linkages between industries. They compile the industrial activity of an economic system into an input-output table that is built around a matrix of monetary transactions. These transactions can be recorded by industry or sector, which are groups of industries involved in similar production processes.

The basic principle of input-output models is that the products sold (outputs) from one industry are purchased (inputs) in the production process by other industries. Therefore, it is plausible that a change in one interindustry linkage can affect the entire system of linkages. For example, the steel industry uses inputs of coal (outputs from the coal industry) to produce goods. These goods are then purchased as inputs in production by other industries, such as the construction industry. What would the impact of a rise in demand for goods produced by the steel industry be on the construction industry, other industries, and the entire economic system? An input-output model could be developed to address these interindustry interdependencies. This type of information provides geographers with a disaggregated view of an economic system in that industries are connected on the basis of buyers and sellers.

Data on the economic linkages between industries are typically collected from surveys of the economic system being modeled and compiled in a table. The table is constructed around a matrix of monetary transactions. The transactions that take place between industries represent a flow of goods and services. They are tabulated based on the value of sales (outputs) and purchases (inputs) of intermediate goods between industries. Like any table, an input-output table consists of a series of columns and rows. The rows of the table reflect the value of sales (outputs) made by each industry. Sales can be further divided to represent sales to final demand. In these categories are included sales of output made to the consumer (households), sales to government (local, state, federal), sales of investment goods (capital equipment), and sales destined to be outside the economic system being modeled (exports). The columns of the input-output table reflect the value of purchases (inputs) that are made by each industry. Purchases can be further divided to represent

<i>Selling Industry</i>	<i>Purchasing Industry</i>	
	X(1)	X(2)
X(1)	x_{11}	x_{12}
X(2)	x_{21}	x_{22}

Table 1 Basic input-output table showing general forward and backward linkages between Industries X and Y

Source: Author.

purchases from value added and purchases of imports. In these categories are included returns to capital (profits and dividends), labor costs (wages and salaries), and purchases of inputs made from outside the economic system being modeled.

Establishing general forward and backward economic linkages between industries is fairly simple with input-output models (see Table 1). In locating the value of sales (outputs) and purchases (inputs) in the table, it is necessary to become familiar with the intersection of rows and columns and what each represents. Consider a linkage between Industries X and Y, with Industry X as the seller. To find the value of sales made from Industry X to industry Y, locate the selling Industry X along the left side of the table and then read across to find the purchasing Industry Y at the top of the table. This would show the value of outputs that are sold from Industry X to Industry Y. Following the previous example, now consider Industry X as the purchaser. To find the value of purchases made by Industry X from Industry Y, locate the buying Industry X along the top of the table and then read down to find the selling Industry Y along the left side of the table. This would show the value of inputs that are purchased by Industry X from Industry Y. Essentially, one-way or multiway economic linkages among industries are possible with input-output analysis. However, analysis of more complicated linkages requires knowledge of matrix algebra.

Input-output models have varying degrees of openness and closure, meaning that there is no

guideline set for determining how many categories of economic activities, final demand, and value are added to include or exclude when developing the model. This largely depends on the analytical purpose of the model. Its use has been extended from the most basic, describing interindustry relations, to include more in-depth and technical analyses of economic systems. Applications of the model include, but are not limited to, forecasting and planning scenarios, economic and policy impact analysis, feasibility studies, and sensitivity analyses. Each of these analyses requires a mathematical manipulation of the transactions table. Commonly, input-output models are used as an alternative to simple economic base and Keynesian models to measure the impacts of multiplier effects within an economic system. With this application, input coefficients that are derived by dividing the purchases in an industry into proportions of total purchases are mathematically altered to represent direct and indirect industry multipliers. The input coefficients can be manipulated to reflect industry-to-industry multipliers in terms of employment, income, and industrial output. For example, in what way does an increase in demand by Industry Y for a good produced by Industry X affect the output of Industry X? However, it should be noted that there are many methods that can be used to calculate economic multipliers from the input-output table.

Regardless of the analytical purpose of input-output models, modeling of an economic system can be undertaken at various scales of geographical inquiry, such as national, regional, state, and metropolitan. In some instances, firm-to-firm interdependencies have been established. Additionally, analyses have compared interindustry relationships across scales so that national, regional, state, and metropolitan economies are compared with other economies at similar geographical scales. To that end, input-output models have been used to help make economic policy decisions.

INSTITUTE OF BRITISH GEOGRAPHERS

For some 60 years, the Institute of British Geographers (IBG) has been the United Kingdom's leading learned society for geographers. It was founded in 1933 and merged with the Royal Geographical Society in 1995.

Learned societies play several major roles in the production and diffusion of knowledge. To promote research, they organize conferences, publish journals, and fund projects; to promote their disciplines, they represent them in a range of arenas. Until the establishment of the IBG, academic geographers in the United Kingdom had no such organization. They were able to meet and publish through the Royal Geographical Society (RGS), the Geographical Association (GA), and the British Association for the Advancement of Science (BA), but each of these had a much wider brief than just supporting academic geography. The GA's mission is to promote geographical education at all levels, and most of its attention focuses on the country's school systems, where it has been an extremely successful advocate for and a change agent in geography. The RGS is a well-established London society that did much to promote geography (especially exploration, discovery, and cartography) and geographical education in the 19th century; by the late 1920s, however, academic research (especially in human

geography) was marginal to its concerns. The BA's annual conferences provide a venue where academic geographers can meet in their separate section, but this body's *raison d'être* and membership is also much wider than that of an academic learned society.

Founding and Early Years

Geography was a very small discipline in U.K. universities in the 1930s. Few departments had been established in the 19th century, and the first full honors degree was not launched until 1917. By the end of the 1930s, virtually every university and university college had a small department—more than five permanent staff members was a rarity. Teaching loads were both heavy and broad, and research activity was not put at a premium. Nevertheless, several meetings—organized by a small group based in University of London colleges—determined that university geographers needed a separate society to organize meetings at which research discussions would predominate and to offer a publication outlet, hence the IBG's establishment. It held an annual residential conference (usually just after the New Year) from the start plus occasional field meetings, and in 1935, it launched its publication *Transactions and Papers of the Institute of British Geographers*.

Growth of the Organization

Until after World War II, the organization was small and its operations limited. Officers were elected, but the tradition of an annual presidential address was only instituted in 1948. More important, *Transactions* did not develop as a regular serial publishing refereed academic papers until 1946. Before that, it published only six separate monographs plus reports of the Institute's annual conferences. In 1959, the Institute organized the first of its international seminars—on applied geography—in Poland. These were used to promote international contacts, most of them with geographers in countries behind the Iron Curtain, although there were

also series of Anglo/German and Indo/British seminars; after 1989, the range of countries widened, but the seminars became less necessary as international travel to major conferences became much easier.

Geography student numbers grew rapidly in the United Kingdom after 1945, and university departments expanded accordingly. The annual conference attracted more participants, and *Transactions* became a regular refereed serial, appearing only once per year until 1962. It became a quarterly in 1976 (when it was relaunched as a "New Series"). A second journal—*Area*, which evolved out of a newsletter—was established as a quarterly journal in 1969. The Institute also sponsored a book series, comprising monographs and major edited collections, in conjunction with commercial publishers.

During the 1960s, reflecting the growth in the number of practicing academic geographers, including graduate students, a major change took place in the IBG's organizational framework with the creation of separate study groups, most of which focused on specific areas of the discipline. Until then, the annual conference had comprised the presentation of unrelated papers, and moves to hold symposia on specific topics were among the stimuli for the study groups. The first was the British Geomorphological Research Group (now the British Society for Geomorphology, which is affiliated with the Geological Society of London as well as the RGS), followed soon after by a Population Studies Group (whose initial *raison d'être* was producing an atlas using 1961 census data) and an Urban Geography group. These enrolled members from both among the Institute's membership and beyond obtained subventions from IBG funds. They organized sessions at the annual conference, plus separate 1-day and residential symposia and other meetings; they generated publications (including monographs, conference proceedings, and, in a few cases, new serials); and they promoted research through allocations of small funds. At about the same time, reflecting its expanding membership and activities, the Institute established a permanently staffed office in London (housed in the RGS building).

The number of study groups (renamed research groups after the 1995 merger) grew rapidly.

(Some, such as the Quantitative Methods group, formally associated with the Institute a few years after its foundation, although others, such as the Association of British Climatologists, remained outside, although occasionally organizing sessions at the IBG's conference.) There are now 22 groups, with provision for the creation of fixed-term working groups to explore particular issues; there is also a separate postgraduate research forum. As well as their annual subventions derived from subscription income (which some groups extend by charging their own subscription), grants and loans can be obtained to fund conferences, research and other projects, travel to meetings (especially for postgraduates), and other activities. The research groups are at the heart of the Institute's activities, being responsible for many of the separate sessions, including plenary lectures as well as paper presentations, at the 3-day annual conference (now held in London in late August and attracting a growing number of international attendees), set within a general conference theme.

Merger of the IBG and RGS

In the early 1990s, moves commenced to merge the IBG with the RGS, and this change was approved by substantial majorities in both organizations despite some concerns expressed by IBG members, a number of whom declined to join the new body. This organization is called the Royal Geographical Society (with the Institute of British Geographers)—RGS (with IBG)—and the IBG's former activities largely occur within the ambit of its Research and Higher Education Division. The IBG's two journals (*Transactions of the IBG*—renamed in 1992; it currently has the highest impact factor of all geography journals included in the ISI/Web of Knowledge database—and *Area*, which caters in particular to postgraduate and early-career authors) have been retained, alongside the RGS's house journal (*The Geographical Journal*, which now specializes in papers having an environmental theme).

INTERACTIVE MAPPING

See Map Animation

INTERGOVERNMENTAL ENVIRONMENTAL ORGANIZATIONS AND INITIATIVES

The environmental issue area is notable for its multiplicity of intergovernmental organizations, numbering nearly 200, with new ones regularly created. Although the United Nations (UN) is a central player in organizing and overseeing many international environmental regulations and initiatives, international environmental governance is conducted largely through organizations created to address specific environmental problems.

The Role of the United Nations

Various organizations within the UN play roles in global environmental governance. The most

central of these is the United Nations Environment Programme (UNEP), a specialized agency of the UN, founded in 1972. UNEP's mission is to play a catalytic role in environmental governance, coordinating environmental efforts by other UN agencies. It has played active roles in environmental monitoring and scientific research on environmental issues and has coordinated and supported the negotiation of international environmental agreements or conventions (treaties). It has also undertaken specific programs to address international environmental issues. Notable among these is its regional seas program, which has negotiated agreements involving 140 states to protect 13 regional seas.

The UN has also held major international conferences on issues relating to environmental issues. The two most influential of these conferences were the United Nations Conference on the Human Environment (UNCHE), held in 1972 in Stockholm, and the United Nations Conference on Environment and Development (UNCED), held in 1992 in Rio de Janeiro. UNCHE involved representatives from 113 states and numerous nongovernmental organizations (NGOs). It produced a Declaration, an Action Plan, and several resolutions, including one that advocated the creation of UNEP.

UNCED focused on the relationship between environment and development. It was attended by representatives of 178 states and featured a parallel "Global Forum" where representatives of 1,500 NGOs met. The conference reiterated the right of states to development and to sovereignty over their natural resources and prioritized the generation of additional financial resources to assist countries with environment and development needs.

Other UN environmental initiatives are worth noting. The World Commission on Environment and Development was established in 1983 at UNEP's recommendation. It produced the report *Our Common Future* in 1987 to give an overview of the difficulties facing the intersecting desires for economic development and environmental protection. The Commission on Sustainable Development was created in 1992 following a recommendation from the Rio Conference. The Millennium Development Goals attempt to improve the lives of people in developing

countries in specific ways by 2015. One goal specifies the need to "ensure environmental sustainability."

International Environmental Organizations

Most intergovernmental environmental cooperation takes place within issue-specific institutions created to address individual environmental problems through specific measures. Each organization has, for the most part, been created through its own negotiation process (usually in the context of a specific treaty). That process results in an anarchic pattern of institutions, where multiple institutions may address different aspects of a given problem or different types of solutions and each organization has a different set of member states.

The earliest intergovernmental institutions focused on what we would now call the sustainable use of species, such as seals, birds, whales, and fish. Different organizations were created to restrict hunting of a given species to a level that would allow reproduction and the indefinite continuation of human use of these resources. These organizations tend to be fairly narrowly focused on a given one or more closely related species, often in a specific region. Examples of existing organizations with this function include the International Whaling Commission and a large number of Regional Fishery Management organizations, which restrict fishing behavior in multiple organizations that focus on species, region, or both.

A different set of organizations addresses the protection of endangered species in a slightly different way, with a focus on preventing extinction and less concern about ensuring continued human use of the species. The two most important organizations of this type are the organization that oversees the Convention on International Trade in Endangered Species of Wild Fauna and Flora and the one for the Convention on Migratory Species. In addition, a UNEP-run secretariat oversees the Convention on Biological Diversity, a process that involves protecting the overall diversity of species and ecosystems.

The International Maritime Organization (IMO) oversees most of the international regulation of

ocean pollution and safety. The IMO issues codes and recommendations to its members and also sponsors intergovernmental conferences leading to the negotiation of binding multilateral conventions on maritime matters, the implementation of which it then oversees.

Other organizations address atmospheric issues. The United Nations Economic Commission for Europe negotiated and implemented multiple agreements to decrease acid rain in Europe. The Ozone Secretariat oversees implementation of the international agreements relating to the protection of the ozone layer. More contentious and less successful so far are international efforts, under the Kyoto Protocol, to decrease emissions of the greenhouse gases that contribute to climate change.

Other intergovernmental environmental institutions are those that address collective action on regional issues, including the Antarctic and the Arctic, and institutions addressing wetlands, desertification, and transboundary movement of hazards, among other issues.

What these intergovernmental institutions have in common is that each is created to address a specific environmental problem. There are similarities across organizations. Many include scientific bodies that are separate from decision-making bodies; most either require unanimous decisions for major policy changes or allow states to opt out of decisions with which they do not agree, and almost all make their primary decisions through regular meetings of the parties. There are linkages between them, sometimes negotiated by necessity, as overlapping mandates can otherwise create conflict or confusion. But, overall, most intergovernmental environmental governance is still done through fairly separate organizations, concerned collectively with natural resources or pollution but addressing these issues through distinct institutional structures.

INTERNATIONAL CRIMINAL COURT

The International Criminal Court (ICC) is the world's first permanent body established to prosecute genocide, crimes against humanity, war crimes, and aggression. The creation of the ICC was the result of decades of advocacy and campaigning by human rights activists, compromises between nation-states, and transformations in the international political order. The hope attached to the ICC is that a permanent court, capable of prosecuting the most powerful perpetrators on the planet, will prevent future atrocities. The ICC's jurisdiction theoretically extends to the entire globe but in practice is subject to intense geopolitical power. The ICC must also navigate complex relationships with nation-states and the local communities most directly affected by extreme violence. The ICC is an intensely interesting phenomenon from a geographical perspective. It is both a product and a producer of globalization—an agent of geographical transformation as well as a result of such processes.

The international community has been imagined to be a superior space for holding perpetrators accountable, as local and national politics repeatedly protected the powerful—a condition referred to as impunity. The observation that “a person stands a greater chance of being tried and judged for killing one human being than for killing 100,000” highlights the dilemmas of accountability in the wake of mass atrocities. Although it is the powerful who are in a position

to commit genocide, and other massive forms of violence, that same power often protects them against prosecution. Proponents of the ICC have argued that conducting trials “elsewhere” provides a “spatial fix” in that international courts may circumvent and therefore overcome local impunity. While courts distant from the location of the atrocities (and outside the national jurisdiction) might prove capable of holding the most powerful perpetrators accountable, critics of doing justice from “afar” argue that the proceedings may have less relevance for the local communities and present troublesome issues concerning national sovereignty.

Historical Background

Interest in a permanent international body devoted to prosecuting war crimes has been expressed at various points in history. During the political polarization of the Cold War period, the superpowers blocked the establishment of an independent international institution devoted to prosecuting war crimes. As the Cold War moved toward its closure (1989–1991), interest returned in the form of a proposal to prosecute drug trafficking in the Caribbean as an international crime. Although the proposal drifted, the idea of an international court remained in the air. Violence during the breakup of the former Yugoslavia spurred the establishment of a war crimes tribunal in 1993 (the International Criminal Tribunal for the former Yugoslavia [ICTY]), and a second tribunal was established following the genocide in Rwanda in 1994 (the International Criminal Tribunal for Rwanda [ICTR]). Subsequent courts were established in Sierra Leone and Cambodia.

While there is a relative consensus concerning the establishment of these ad hoc tribunals, certain powerful sectors remained averse to a permanent international court that would have jurisdiction over every potential perpetrator on the planet. Among those objecting were the likely subjects—the notoriously violent dictators and despots who had every reason to resist judicial accountability. Objections also came from the U.S. government, which expressed fears that submission to the jurisdiction of an international

court would undermine U.S. sovereignty and its potential for global military activity. While the United States had supported “international justice” for the peoples of Rwanda, the former Yugoslavia, Sierra Leone, and Cambodia, it was far less willing to consider such courts for its own nationals.

Formation of the ICC

The situation came to a head during the conference held in Rome in 1998 to draft and approve a statute for an international criminal court. For 5 weeks, the U.S. delegation to the United Nations (UN) conference wrestled with the rest of the world over the ICC treaty. Washington strenuously objected to elements in the treaty that gave the ICC its powers and, in the minds of the vast majority of the other participants, made the court viable. The United States insisted on conditions that would essentially make it impossible to try an American. Frustrated delegates worried that the resultant ICC would be either weakened by “American exceptionalism” or weakened by the lack of involvement of the United States.

Certain accommodations and compromises were made in an attempt to bring the United States on board. The principle of “complementarity” was among the most significant. Complementarity assures that national jurisdictions have the first obligation to prosecute. It is only when a nation-state proves “unable or unwilling” to prosecute its suspected criminals that the ICC can assume jurisdiction. In a world with less impunity, Colombian national courts would prosecute Colombians, Burmese courts would prosecute Burmese, and so on. But if national courts fail, the ICC is there to act.

A further restriction on the ICC’s powers is the restricted ways in which a case can be brought to the ICC. There are three “trigger” mechanisms that allow the ICC to take up a case. A case can be heard pursuant to

1. a state party referral (a party to the Rome Statute requests the ICC’s intervention);
2. a Security Council referral; or

3. *proprio motu*, in which the prosecutor may initiate investigations on the basis of information on crimes within the jurisdiction of the court.

In particular, allowing the Security Council a veto over the court, as the Security Council can effectively shut down an investigation/prosecution by ordering the ICC to abstain from such action for a year (renewed on a yearly basis), effectively provided the United States with the ability to shut down any case. Despite these appeasements, the United States became increasingly isolated, watching as its allies coalesced into the group of “like-minded nations.”

A notable aspect of the formation of the ICC was the role of international nongovernmental organizations (NGOs). International social movements were essential to the creation and promotion of the ICC. A group of more than 800 NGOs established the Coalition for the International Criminal Court and participated at unprecedented levels in the drafting of the Rome Statute, the lobbying of state parties, and the hard, grassroots work of bringing diverse national constitutions in line with international aspirations regarding human rights norms. Additionally, victims were to have a greater role both in the prosecution and in terms of the possibility of receiving reparations, provisions supported by the NGOs.

When the Rome Statute was drafted and approved in 1998, most observers close to the process believed that it would actually take many years (decades) for the ICC to materialize. In fact, the process moved quite quickly to fruition. By 2002, the Rome Statute had garnered the requisite 60 signatories and came into effect. The Dutch government agreed to host the offices of the ICC in The Hague, a city with an established community of international institutions. The Dutch government also provided substantial financing for the ICC’s infrastructure and passed national legislation associated with the presence on its territory of suspected war criminals and others who would be participating in such trials. In its gestation, the ICC also benefited from its location in The Hague in that many of the staff had significant expertise and experience from working in the ICTY.

When the ICC started in 2002–2003, its staff was extremely conscious of the vulnerability of the institution. At the ICC’s first major press conference in July 2003, the chief prosecutor sought to explain how the fledgling court was going to proceed among a universe of possible crimes. Extreme violence was found everywhere, but what to count as legitimate warfare and what to declare a crime against humanity? The ICC in its initial statements stuck to careful ground, narrowly interpreting its jurisdiction and stressing the limits of its resources. Temporally, the ICC’s jurisdiction covered crimes committed after it came into effect, which meant that any crimes committed before July 2002 were off limits. But by far the question of how the ICC would act *spatially*—how it would interpret its territorial jurisdiction—was the most provocative. In theory, the ICC is distinct in that it can exert jurisdiction (with justification) anywhere on Earth. This is its promise as well as its problem. Its very strength—its universal reach—is also the source of the enmity it has attracted.

Impacts of the ICC

In its first 5 yrs. (years) of operation, the ICC can be analyzed through the lens of its actions and its omissions—cases taken and others ignored or rejected. The most obvious issue is that the four cases taken in the first 5 yrs. have all been in Africa: Uganda, the Democratic Republic of the Congo (DRC), Sudan, and the Central African Republic. That all 12 indictees are African men has raised charges of neocolonialism. There are concerns that the ICC is yet another version of “victor’s justice” in which the powerful (in this case the wealthy “Western” nations, which dominate the institutions of the international community, including the permanent members of the UN Security Council) use institutions such as the police and judiciary to criminalize the actions of the weak while simultaneously legitimizing their own violence. Of its omissions, the ICC controversially rejected requests to investigate alleged crimes in Iraq.

The ICC has been lauded as the culmination of millennial aspirations for justice and the future protection of human rights. Yet, to date, the

“international” court has indicted only African men. Granted, these suspects are accused of heinous violence—rape, child abduction, forcing family members to kill each other—documented in detail by reputable human rights watchdog organizations. Yet their violence and alleged crimes exist alongside those of the state, which happens to be the same authorities that cooperate with the ICC. In the case of Uganda, the prosecutor has investigated and indicted the bizarre, reclusive, and quite possibly insane Joseph Kony of the Lord’s Resistance Army but has (to date) ignored the violations committed by the Ugandan State. With the exception of an investigation into the actions of Sudan’s president, the ICC failed to challenge state-power.

As of 2009, 139 states had signed, representing all regions of the world, including 11 in Asia, 41 in Africa, 26 in Latin America and the Caribbean, 44 in Europe, and 22 in the Middle East and North Africa, as well as Canada, Australia, New Zealand, and several Pacific Ocean states. Future issues associated with prosecuting and preventing atrocities will likely exhibit complex, overlapping, and intertwined geographies. International institutions are proliferating, but local and national politics and social movements remain intense; rather than “overshadowed” by the international, local and regional practices seem fully engaged and inflamed. The ICC’s activities (and its absences) during its gestation and infancy illustrate complicated social, political, and legal geographies.

INTERNATIONAL ENVIRONMENTAL MOVEMENTS

International environmental movements are social movements that contest, at an international and sometimes global scale, different kinds of global environmental degradation. They try to show that this degradation is largely the result of current patterns of production, consumption, transportation, and energy use and, more generally, the prevailing organization of social life and the present international economic and political order. In arguing that global environmental degradation is one of the “routine consequences of modernity,” many international environmental movements challenge the very basis of modern society. International environmental movements are important because they define problems, propose solution strategies, and raise social consciousness with respect to global environmental problems such as climate change, biodiversity loss, deforestation, and desertification.

This entry describes the origin and development of international environmental movements, presents several examples of international environmental movement action campaigns and actors, and briefly sketches the context in which international environmental movements operate and the structure of international political opportunities.

Origins and Development

Environmental movements originally constituted one specific part of the “new social movements” that emerged in Western Europe and the United States from the late 1960s onward. Other examples of new social movements include the women’s, peace, and human rights movements, as well as the anti-Vietnam War and civil rights movements in the United States. New social movements distinguished themselves from “old” movements such as the labor movement by their emphasis on “postmaterialist” rather than materialist values; by their predominantly “new middle class” constituency; by their decentralized rather than hierarchical organizational structure; by their distrust in traditional, established ways

of doing politics; by their unconventional action forms; and, finally, by their orientation at the development of new individual and collective identities. New social movements pointed to the “dark sides” of progress, environmental degradation being the most important case in point.

From the 1960s onward, environmental problems have been defined on an ever larger geographical scale: local, national, regional, and global. In the 1960s, local environmental movements typically struggled against polluting factories, new motorways, and the illegal dumping of waste. In the 1970s, movements struggled against the plans of national governments to build new nuclear energy plants and in favor of strong national legislation to halt the pollution of air, water, and soil. From the 1980s onward, environmental movements discovered the transboundary character of environmental pollution, for instance, acid rain, and started to plead for stronger regional (e.g., European) solutions. Finally, from the 1992 United Nations Conference on Environment and Development (UNCED) onward, the global character of many environmental problems was acknowledged: climate change, biodiversity loss, deforestation. UNCED brought together thousands of environmental groups from all over the world: It enabled the growth of contacts between these groups, which was reinforced by the facilities offered by the developments in telecommunication (e-mail, Internet).

Action Campaigns and Actors

Antinuclear Movement

One of the first international environmental movement campaigns was the Western European movement against nuclear energy in the 1970s and early 1980s. Around 1970, many Western European governments had decided to build substantial numbers of (new) nuclear power plants in order to decrease their dependency on oil for electricity generation, and in all those countries antinuclear movements arose. These movements showed striking similarities to the ideal type of a new social movement as described above. The reasons for resistance, for instance, could be labeled as “postmaterialist,” although they

widely differed from one country to another. In some cases, a nuclear plant was considered to threaten the character of the local community and thus to decrease local autonomy. In other cases, nuclear energy and nuclear weapons were seen as different sides of the very same coin. Additional reasons for resistance included the fear of militarization of society due to the ever stronger measures to protect nuclear plants, the unsolved problem of nuclear waste, the resistance to capitalism, and so on. Antinuclear movement activists disproportionately emerged from the “new middle class”; they organized themselves through autonomous local networks, distrusted institutional politics, and fought their case through road blockades, tent camps, and (sometimes) violent confrontations with the police. Activists from different countries struggled shoulder to shoulder, resulting in the development of new, international, and “countercultural” individual and collective identities.

Movement Against Genetically Modified Organisms

The first truly European, or European Union (EU)-wide, international environmental movement was the movement against genetically modified organisms (GMOs). From the mid 1990s onward, seed companies such as Monsanto had tried to introduce genetically modified soy and maize in the European market. Although biotechnology companies and parts of the food sector claimed that consuming GMOs would become inevitable, international environmental NGOs such as Greenpeace and Friends of the Earth organized a massive resistance movement against them. The result was an EU-wide moratorium that lasted until 2004, and public opinion surveys reveal that time and again a vast majority of the European public rejects genetically modified food and feed.

The movement against GMOs consisted of three sectors from society: environmental groups, consumer groups, and farmers. Due to this broad constituency, the movement was able to tap not only into numerous specialized issue publics and their social networks (e.g., organic farmers’ associations) but also into more diffuse constituencies (e.g., supporters of Greenpeace). The success of

the campaign, however, widely differed from one country to another. In France, for instance, the two most important mobilizing groups were Greenpeace France and the farmer's organization Confédération Paysanne (CP), and this cooperation turned out to be very successful. CP's fame reached its peak following the August 1999 destruction of a McDonald's franchise in Millau and the mediagenic performance of its charismatic leader José Bové.

The success of the campaign in France, and also in countries such as Italy and Spain, can be explained by the fact that GMOs were discursively linked with the expansion of neoliberalism, the increase in scale, and the accompanying loss of autonomy, values, and culture for small farmers. GMOs were brought on the market by multinational corporations such as Monsanto in a period when this kind of company was considered among the largest and most greedy beneficiaries of neoliberalism.

Another impact of the European movement against GMOs was the establishment of the "Network of GMO Free Regions" on November 4, 2003. On that day, the ministers of agriculture from 10 European regions, including Upper Austria and Tuscany, signed a document asserting the right of regions to forbid GMOs within their territories. The network has since grown to include 39 major regions from six different countries: Austria, France, Greece, Italy, Spain, and the United Kingdom.

The Greenbelt Movement

An example of a Southern international environmental movement is the Greenbelt movement. The Greenbelt movement provides income and sustenance to millions of people in Kenya through the planting of trees. It also conducts educational campaigns to raise awareness about women's rights, civic empowerment, and the environment throughout Kenya and Africa. The movement was founded by Wangari Maathai, winner of the 2004 Nobel Peace Prize.

Global Environmental Justice

Other present-day international environmental movements include those against the international

trade in toxic waste, the destruction of tropical rain forests, and climate change. The campaigns of these movements are increasingly framed through the perspective of "global environmental justice." Although most actions take place at the local, regional, or national level, these actions are typically coordinated by international or global networks: the Basel Action Network (BAN), the Rainforest Action Network (RAN) and, most important, the Climate Action Network (CAN).

The Climate Action Network

The CAN consists of more than 365 environmental groups working to promote government and individual action to limit human-induced climate change to ecologically sustainable levels. Member groups include national branches of international environmental NGOs such as Greenpeace, World Wide Fund for Nature (WWF), and Friends of the Earth International (FoEI) and also local and regional organizations. CAN members work to achieve their goals through the coordination of information exchange and NGO strategies on international, regional, and national climate issues. Strategies vary from building a dike consisting of sandbags around the conference center where the 2000 UN Climate Summit was held, to lobbying government in favor of national-level climate laws, to solar energy demonstration projects. CAN has 7 regional offices that coordinate these efforts in Africa, Central and Eastern Europe, Europe, Latin America, North America, South Asia, and southeast Asia.

International Environmental Movements and Political Opportunities

International environmental movements try to reach their goals through all kinds of interactions with business, the general public, and, most of all, political authorities. Political opportunities refer to the specific features of a political system that help explain the different action repertoires, organizational forms, and impacts of these movements. For instance, political authorities that repress social movements provoke the application of confrontational movement strategies (demonstrations, blockades, site occupations), whereas

political elites that try to integrate challengers into the political system discourage these radical strategies in favor of a more moderate action repertoire (negotiations, participation in advisory boards, etc.). Similarly, centralized states with limited decision-making competencies for local authorities encourage the foundation of social movements and social movement organizations at the national level (e.g., France, the Netherlands), whereas decentralized states with substantial decision-making competencies at the local or regional level foster the foundation of movements at those levels (e.g., Germany, Switzerland).

The concept of “political opportunity structure” (POS) has been applied mainly to the national level to explain the differences in action repertoires, organizational forms, and impacts of social movements between different countries. International environmental movements, however, operate at the international level, interact with international political authorities, and, consequently, are confronted with international political opportunity structures. Examples of international institutions that are relevant for international environmental movements include the United Nations (the “producer” of international environmental regimes), European Union (EU-wide environmental “directives”), World Trade Organization (WTO; trade regulations with major environmental impacts), and World Bank (loans for the construction of large dams in developing countries). These institutions widely differ with respect to their formal points of access for international environmental movements and NGOs, the responsiveness of the political elites to movement demands, the homogeneity of the institution’s political elite, and, finally, the institution’s policy implementation capacity. These four dimensions of international POS can be summarized as follows:

- A formal institutional structure (open/closed)
- Informal elite strategies (integrative/exclusive)
- Configuration of power (divided elite/united elite)
- A political output structure (weak/strong)

Whereas, for instance, the formal institutional structure of the United Nations (UN) and the EU can be qualified as relatively open to social

movements and social movement organizations, the World Bank and the WTO are much more closed. As predicted by POS theory, international environmental movements generally try to influence UN and EU decisions by lobbying and participating in decision-making procedures, whereas they use more radical strategies against World Bank and WTO policies. The large-scale resistance against World Bank–sponsored large dams in India and Brazil and against WTO-induced free-trade rules that are damaging for the environment are cases in point.

On the other hand, the political output structure of the World Bank and the WTO is very strong. Decisions taken by the World Bank and the WTO are almost always effectuated, a feature missing for many UN and EU decisions. For international environmental movements, it is very difficult to successfully influence World Bank and WTO policies, but, if successful, major policy changes may be the result.

INTERNATIONAL ENVIRONMENTAL NGOS

International environmental NGOs are nongovernmental organizations that, on an international and sometimes global scale, try to influence decision making by governments, corporations, and other social and political organizations, as well as by individual citizens, in order to stop or diminish environmental degradation.

International environmental NGOs can take four different forms, each with their own specific features: (1) international mass membership organizations, (2) national mass membership organizations operating at an international level, (3) international environmental think tanks, and (4) international environmental umbrella organizations. In the following sections, these four categories will be addressed one by one.

International Environmental Mass Membership Organizations

The three most important international mass membership organizations are Greenpeace, World Wide Fund for Nature (WWF), and Friends of the Earth International (FoEI).

Greenpeace

Greenpeace, founded in 1971, is a global campaigning organization with branches in 42 countries and a total constituency of more than 2.5 million. The Dutch and German branches are among its largest, each with 500,000-plus supporters, as are the British and the North American branches, each with about 250,000 supporters.

The origin of Greenpeace is in the peace rather than the environmental movement. Its very first target was the United States testing nuclear devices in Amchitka, Alaska, and nuclear weapons have been a topic of contention ever since. In 1995, Greenpeace's ship *Rainbow Warrior* was bombed by the French army after it entered the waters of the Moruroa atoll in the South Pacific to prevent French nuclear testing.

Greenpeace has played a pivotal role in the adoption of a ban on toxic waste exports to less developed countries, a moratorium on commercial whaling, and bans on the dumping at sea of radioactive and industrial waste. Present priorities include climate change, preservation of the oceans, tropical rain forests, sustainable agriculture, and toxic chemicals. Greenpeace tries to reach its goals by lobbying, by scientific research, and, most of all, by its unconventional action repertoire. Due to its sophisticated communication strategy, Greenpeace has been very successful in raising environmental consciousness.

World Wide Fund for Nature

The WWF, founded in 1961, is the world's largest conservation organization with a joint constituency of more than 5 million. Its largest national branches include the North American and the Dutch ones, each with about 1 million supporters. WWF started as a conservation organization with hundreds of conservation projects, mainly in southern countries, such as the restoration of orangutan habitats and the establishment of panda reserves. In the past couple of decades, it has gradually broadened its mission to stopping the degradation of the planet's natural environment, resulting in coverage of topics such as pollution and climate change. However, contrary to Greenpeace, WWF never applies confrontational action strategies.

Friends of the Earth International

FoEI is the world's largest grassroots environmental network, uniting 69 national member groups and some 5,000 local activist groups on almost every continent. FoEI has more than 2 million members and supporters worldwide; among its largest branches are the German, the British, and the Dutch ones. FoEI's ideological base

Members of the World Wide Fund for Nature set up 1,600 papier-mâché pandas on October 18, 2008, to symbolize the 1,600 pandas left on Earth and to call on people to help reverse the deterioration of our natural environment. The installation was on the Parvis des Libertés et des Droits d'Homme at the Trocadéro esplanade in Paris.

Source: François Guillot/AFP/Getty Images.

could be summarized as “political ecology”: FoEI challenges the current model of economic and corporate globalization. To protect the Earth against further environmental degradation, FoEI aims to increase public participation and democratic decision making and to stimulate grassroots activism.

National Mass Membership Organizations Operating at an International Level

The second form that international environmental NGOs can take is the national, largely U.S.-based, mass membership organizations that have developed international programs. Groups belonging to this category include the National Wildlife Federation (5 million members and supporters), National Resources Defense Council

(NRDC; 1.2 million), Sierra Club (730,000), National Audubon Society (550,000), and Environmental Defense Fund (EDF; 500,000). In sum, these five groups have a staff of well over 1,000 and a joint budget of around \$200 million.

The distinctive feature of this category is its prominent role in influencing negotiations on multilateral environmental agreements. Sierra Club, Audubon Society, and Wildlife Federation are highly involved in international conservation issues such as the protection of tropical rain forests and the United Nations Biodiversity Convention. EDF and NRDC have played an effective role in the negotiations on climate change and ozone layer depletion and have also helped reshape the policies of the multilateral development banks.

Another organization belonging to this category is The Nature Conservancy, a U.S.-based conservation group with more than 1 million members and annual revenues of more than US\$1 billion. The Nature Conservancy has protected more than 69,000 km² (square kilometers) in the United States and more than 473,000 km² internationally.

International Environmental Think Tanks

International environmental think tanks are research institutes that are loosely tied to the problem definitions and solution strategies of international environmental movements. Examples include the German Öko-Institute, the American World Watch Institute and the World Resources Institute, and the London-based International Institute for Environment and Development (IIED). IIED, founded 1971, works globally through a wide range of relationships with partners across the developing world. These partners diverge from smallholder farmers and national governments to regional NGOs and global institutions. At all these levels, IIED provides expertise in achieving sustainable development. Current priorities include the strengthening of local rights to land and natural resources, strengthening corporate responsibility for social and environmental gains, and monitoring the impact of Northern government policy.

International Environmental Umbrella Organizations

International umbrella organizations are “organizations of organizations,” founded to represent the interests of their member groups at a regional or global level. Examples include the European Federation for Transport and Environment and the European Environmental Bureau (EEB). The EEB, founded in 1974, is a confederation of more than 140 environmental NGOs from 31 European countries, with a combined membership of about 14 million. It is the lobbying branch of the European environmental movement at the EU level with direct access to the European Commission.

INTERNATIONAL GEOGRAPHICAL UNION

The International Geographical Union (IGU) is the international organization of academic geographers, established in 1922 in Brussels following a series of international geographical meetings, the first of which was held at Antwerp in 1871. The objectives of the IGU are to promote the study of geographical problems; to initiate and coordinate geographical research requiring international cooperation and to promote its scientific discussion and publication; to provide for the participation of geographers in the work of relevant international organizations; to facilitate the collection and diffusion of geographical data and documentation in and between all member countries; to promote meetings of the IGU, regional conferences between the international geographical congresses, and other meetings in furtherance of the objectives of the Union; to participate in any other appropriate form of international cooperation with the object of advancing the study and application of geography; and to promote

international standardization or compatibility of methods, nomenclature, and symbols employed in geography.

The IGU belongs to the International Council on Science and to the International Social Sciences Council and recognizes them as providing coordinating and representative bodies for the international organization of science and the social sciences, respectively.

IGU membership is normally by country, currently 98, rather than by individuals, national professional organizations, or national societies. Member countries are expected to establish committees for the IGU, frequently functioning through national academies of science. They promote the objectives of the Union in their respective countries, notably the international aspects. They also diffuse information from the executive committee to geographers in their country. Associate country membership applies to small or emerging geographical communities. A third membership class is of corresponding members who may be either individuals or institutions.

The IGU functions through its general assembly, consisting of all member countries and meeting every congress. The assembly elects the executive committee, which consists of the president, the immediate past president, seven other vice presidents, and a secretary-general. The president, the secretary-general, and the executive committee manage the Union's activities, assisted by a secretariat located close to the office of the secretary-general, who serves also as the treasurer.

The working languages of the IGU are English and French. The Union holds a congress every 4 yrs. (years) and a regional conference every 2 yrs. between congresses. Locations for these meetings are competitive. The IGU maintains the Home of Geography, located within the premises of the Italian Geographical Society in Rome, which publishes a newsletter and specialized monographs. The main organ for continuous scientific work is the commissions, currently numbering 36, in addition to task forces (currently four) and special committees (currently two). The commissions reflect both veteran and novel specialties in geography. Commissions are approved by the general assembly, and they constitute a steering committee of 10 to 12 geographers from different countries and the commission itself, to which any

geographers may join. Commissions hold meetings, workshops, and field trips; develop joint research projects; and publish newsletters and journals and exchange information through mailing lists.

INTERNATIONAL MONETARY FUND

The International Monetary Fund (IMF) is a treaty-based, voluntary association of countries based on their real or potential impacts on the world's economy. It currently controls assets amounting to US\$215 billion and has 182 member countries. Unlike the World Bank, the other "pillar" of the world economy, the IMF has no subsidiaries or affiliates. Its highest authority resides with the Board of Governors (which meets annually), each of whom is appointed by a member country.

IMF membership has varied over time, as has its role and responsibilities in world affairs. The evolution of the IMF can roughly be divided into phases based on the degree of functionality, relevance, and shifting purpose. Initially, the IMF was established at the Bretton Woods Conference (along with the World Bank) in New Hampshire with the signing of the Articles of Agreement in July 1944 and declaration of exchange values by the 44 member countries at the first meeting in 1946. However, most economists and historians disregard the impacts of the early IMF since the most important signatories (Western industrial democracies) refused to establish rules regarding the conversion of each other's currencies into their specific reserves until December 27, 1958.

From that point until the decision by the American President Richard Nixon on August 15, 1971, to refuse conversion of U.S. notes of exchange into gold from the Federal Reserve, the IMF operated to stabilize exchange rates by setting “pegs” that regulated exchange values. This policy constrained the degree to which individual countries could pursue deflationary valuations to stimulate exports or foreign direct investment (FDI) but ensured that variations in exchange rates would also be constrained. In addition, it was believed that the pegs would alleviate uncertainty regarding the risks of FDI and thus help spur reconstruction following World War II. This peg arrangement reflected the desire of the Bretton-Woods signatories to incorporate both the advantages of the prewar gold standard and the flexibility of floating exchange rates that were popular during the interwar years. In addition, it was believed that the disadvantages of submission to the vagaries of the business cycle under the gold standard and the dangers of under- or overvaluation and trade imbalances under the floating exchange rate system could be avoided.

However, the IMF proved difficult to get going. It was generally acknowledged at Bretton-Woods that although the United States had emerged from World War II as the preeminent economic power, it nonetheless suffered from a shortage of currency in relation to its productive output. The U.S. contingent was accordingly wary of arrangements that would help other countries peg their currencies at values that would hurt U.S. exports. Thus, this early version of the IMF lacked effective enforcement mechanisms. This very point was hotly debated during Bretton-Woods, with the noted economist John Maynard Keynes arguing for a stronger, more credit-oriented institution that would have its own currency and accounts (essentially, a bank), while others (led by Harry Dexter White, Chief International Economist at the U.S. Treasury) pushed for IMF management of a pool of member currencies. In the end, a compromise was reached that resulted in a relatively weak version of the IMF in comparison with the current incarnation. With convertibility of member currencies established in 1959, however, the IMF managed to oversee a generally sustained, long period of expanded world trade, economic growth,

and stability within the industrialized democracies until 1970. With the adoption of floating exchange rates in 1973, the IMF began a 5-yr. (year) period of restructuring and adjustment that led to amendment of the constitution in 1978. The most notable adjustment was the replacement of the mechanism of pegged exchange rates with frequent consultation (usually once a year), technical advice, policy support, and loan conditions to ensure that member countries follow policies designed to support economic stability.

The IMF Today

In its current incarnation, the core mission of the IMF broadly remains the same as its founders’ intention: to ensure a smooth, orderly world economy by helping member countries find the most accurate price for their currencies. However, following the debt crises of the 1990s in Brazil, Russia, and five Asian countries (to which the IMF had extended more than US\$100 billion in credit), the IMF’s expanded role of structural adjustment of economies has exacerbated or done little to forestall economic or political instability. A lack of expertise in the area of structural adjustment is unsurprising, as it was a relatively minor function of the IMF at its original inception. The enforcement mechanism was intended to prevent countries from pursuing policies detrimental to their trading partners, not to restructure economies to facilitate smooth participation in the global economy. Similar to the World Bank, the IMF can now use its power as a lender over countries struggling to honor their currency exchange values through the imposition of “conditionalities” that the debtor country must follow to receive a loan. These conditionalities can range from fiscal policy (curtailing domestic spending) to trade policy (increased liberalization) to monetary policy (tightly controlling reserves to discourage inflation). The logic of the conditionalities is that they are designed to ensure that the borrowing country will be able to repay the loan by stimulating exports and increasing the government’s money supply without leading to inflation. However, there are significant political costs attached to radical economic restructuring, which the IMF has been criticized for not recognizing.

Ironically, this restructuring role for the IMF would have been difficult for the architects of the system to recognize. Their focus was simply on ensuring stability within the international monetary system. Over time, the enforcement mechanism designed to ensure resolution of balance-of-payments crises (balance of payments refers to all outstanding payments and debts the residents of a country owe to other countries) and beggar-thy-neighbor monetary policies (using currency devaluation to reduce foreign debt or stimulate exports) has evolved into a restructuring tool for emerging economies. The most obvious turning point in funds development was the closure of the “gold window” by the United States; this unilateral move highlighted a fundamental limitation in the fund’s power to regulate financial matters. This power was largely ineffectual for industrialized countries that maintained large payment surpluses and was certainly impotent where the interests of the largest member of the fund, the United States, were diametrically opposed to IMF’s goals.

The current structure still reflects this imbalance in its allocation of voting power—the United States has 18% of the existing voting rights, more than double of any other country. However, calls for more democratic participation by emerging economies in the IMF have been met with some reforms. Currently, there are more than 180 member countries that receive voting rights in accordance with their level of international trade, national income, and international reserve holdings. In terms of upper-level management, however, the fund continues to reflect dominance by the founding countries. The managing director and deputy managing director rotate between a European and an American (the current director is from France, the first deputy from the United States), the IMF is headquartered in Washington, D.C., and the 24 executive directors in charge of day-to-day operations are dominated by the original signatories.

China, Russia, and Saudi Arabia also have the right to appoint one executive director each, while as a whole, the remaining member countries are allowed to nominate one director to represent all of them. Voting rights are also a function of Special Drawing Rights (SDR), which are based on national income, reserves, and trade balance. The formula applied equates one vote for every 100,000 SDR, the quotas for which are reviewed

every 5 yrs. at a minimum. These quotas have increased steadily as subscription (membership) has increased over time, and if a member country does not pay its subscription, it does not receive its quota of SDR and, hence, has no voting rights. However, since the fund relies on subscriptions to finance loans and operate, countries that contribute a large share of subscriptions relative to the rest of the countries maintain a disproportionate amount of influence. This imbalance can lead to a compromise of the IMF’s core mission to maintain long-term stability in exchange rate relations as certain countries may benefit from less regulation of capital markets.

Subscriptions are not the only source of funding for the IMF, however. In addition, the IMF may borrow funds from the G-10 countries (Canada, Belgium, France, Germany, Italy, the Netherlands, Japan, Sweden, the United Kingdom, and the United States) plus Switzerland under the General Arrangements to Borrow (GAB). The GAB was used in 1998 to settle Russia’s balance-of-payments crisis. The GAB was expanded by the fund shortly afterward and currently has 17,000 million in SDR set aside for balance-of-payment crises.

The enhanced role of restructuring and policy reform during the 1980s and the resulting criticisms from that period and the notable failures during the 1990s have led to some reform. Shortly after the first round of crises, the fund reorganized the Enhanced Structural Adjustment Facility as the Poverty Reduction and Growth Facility. The new version of the facility was charged with identifying poorer countries that were able to achieve the twin goals of poverty reduction and sustainable growth. A total of 77 countries were identified as eligible for a loan in the amount of 140% of their quota payable at 0.5% interest over 10 yrs. This initiative to assist poorer countries was mirrored by the World Bank the same year with a program to aid Heavily Indebted Poor Countries (HIPC), 33 of which were in Africa, with debt relief. The condition for debt relief was that applicants must present and follow through on a yearlong strategy for reducing poverty and encouraging sustainable economic growth. Shortly after the option was developed, Uganda became the first country to apply for and receive debt relief under the Poverty Reduction and Growth Facility mechanism.

In April 2001, the IMF further expanded its surveillance functions, shifting greater emphasis toward identifying money-laundering organizations with terrorist links and pushing developing countries to exercise greater oversight of the offshore financial centers (OFC) that commonly provide money-laundering services. In 2002, a director for special operations was appointed to handle crisis response. By 2003, the fund responded to calls for more voluntary debt-restructuring methods by pushing for greater use of collective action clauses in international bond contracts. In 2006, the Monetary and Capital Markets Department was formed to strengthen fund surveillance of international finance. By 2007, roughly 90% of the fund members had agreed to increased oversight of payments, transfers, and currency arrangements.

The final arena in which the IMF has attempted reform has been its capacity to provide technical assistance. In 1993, the IMF opened regional centers in the developing and developed world to provide continuous advice from Special Missions and Resident Advisors to their respective governments on all aspects of macroeconomic issues. In addition, the IMF has maintained the IMF Institute as a training center for government officials from member nations. Postcrises, the IMF revamped the curricula of the IMF Institute to include the political impacts of the standard IMF conditionalities.

The crises of the 1990s demonstrated that the growth of international capital markets and overall connectedness of world economies by globalization eroded the extent to which floating rates insulate countries from external shocks. Nevertheless, the role of the IMF as a forum for exchange rate management continues. As of 2008, the IMF has acknowledged the need for greater focus on financial crisis prevention rather than response and has added an additional purpose of providing economic and statistical analysis on behalf of their other missions, developing financial sector Reports on the Observance and Codes (ROSC), which detail standards in the areas of transparency (for fiscal, monetary, and financial policy) at the behest of member countries wishing to improve oversight of their financial sector.

INTERNATIONAL WATERSHED MANAGEMENT

International watershed management refers to the multistakeholder process of creation, implementation, and monitoring of plans, projects, and programs aimed at the sustenance and enhancement of watershed functions across national boundaries. The complexity of the term reflects the complexity of approaching watershed management at an international or transboundary scale. At national levels, most countries have environmental laws that dictate the planning approaches and actions that agencies need to take to manage their watersheds, while at an international level there is no legislature that regulates how transboundary watersheds are managed. As a result, international watershed management can become a contentious issue and is generally based on bilateral or multilateral agreements between and among stakeholders. Increasingly, forecasts of climate change and economic shifts single out water resources management as a critical focal point for natural resources management and planning and a potential conflictual arena in sensitive

regions. The complexity of this issue and the varying types of expertise required for problem solving and decision making make it relevant to various subfields of geography, for example, physical, social, economic, and political.

An international or transboundary watershed is defined as all the territory that contributes to a stream, with at least one tributary crossing a political boundary. Sixty percent of the Earth's freshwater bodies fall within transboundary basins. Creating effective transboundary watershed management requires the establishment of working relations and sound communication between stakeholders. Especially in regions with a history of water resources management conflicts—for example, the Colorado, Nile, Tiger-Euphrates, Indus, Mekong, and Incomati Basins or those in the Middle East—the lack of explicit collaborations, communication between the responsible riparian parties, and implementation of professional conflict resolution strategies has contributed to prolonging a crisis state.

Conventions and Treaties

The Convention on the Protection and Use of Transboundary Watercourses and International Lakes encourages riparian parties to enter into bilateral or multilateral agreements based on, for example, water quality and quantity—monitoring data exchanges. This convention is based on *The Helsinki Rules on the Uses of the Waters of International Rivers*, published by the International Law Association in 1966, which embraces the theory of equitable utilization and by which each riparian state in an international basin is entitled to a “reasonable and equitable share” of the watercourse and commits to not cause “substantial injury” to coriparian states. The United Nations Convention on the Law of the Non-Navigational Uses of International Watercourses, adopted in 1997, added to the equitable and reasonable utilization of waters clauses, such as protection of the aquatic environment and promotion of cooperative management mechanisms, and made further provisions on data and information exchange and mechanisms for conflict resolution. However, the treaty most invoked internationally for watershed protection and management is the Ramsar Convention on Wetlands (officially called

The Convention on Wetlands of International Importance), which took effect on December 21, 1975, with presently 158 signatories, and addresses the protection of wetland habitats.

Establishing Effective International Watershed Management

Effective international watershed management requires comprehensive and multidisciplinary approaches and a flexible and integrative framework for addressing the biophysical, socioeconomic, and governance issues affecting water resources and their equitable distribution and use. There are several stages in the planning and management process for watersheds. Throughout the process, care must be taken that basic hydro-diplomacy principles are considered and that continued stakeholder consultation and public participation are ensured. The first step in the management process is establishing plan parameters and objectives, followed by identification of watershed components and processes (also known as a watershed physical inventory), which can be more or less detailed depending on the context. Once the basic basin characteristics and management objectives are set, the stakeholder consultation process to develop practical management options and alternatives can begin. Crucial steps in the development of a management strategy include determination of the legal and policy implications that pertain to all nations participating in the consultation process and a detailed assessment of the environmental, socioeconomic, and political impacts of the plan. While theoretically the steps leading to the top-down implementation of a viable watershed management plan are straightforward, in practice there are several limitations. These include lack of data; reduced accessibility in parts of the basin; inadequate funding; bureaucratic and administrative hurdles dictated by the different political situations of stakeholders; low levels of public awareness, information, and involvement; competing interests; and the relative lack of an international regulatory body or set of water laws pertaining to transboundary watershed management.

Alternative approaches to the top-down integrated water resources management (IWRM) strategy described above include the creation of

bottom-up institutions, through the decentralization of multigovernment services and governance to local and regional authorities, private enterprises, and communities. This approach, known as community-based water resources management (CBWRM), grew from the need to fill the gap in policy making at the regional, interstate level and implementation at the local level, since policies and management plans devised through formal interstate consultations rely on implementation at local levels. Apart from the IWRM or CBWRM strategies, other successful approaches include an adaptive watershed management approach practiced in the Columbia River Basin of the United States and an ecosystem-based river basin management approach practiced in the Ili-Balkhash Basin in Central Asia. These approaches are not mutually exclusive and, to be functional, need to sustainably integrate biophysical, socioeconomic, and political and varying levels of institutional elements in river basins. The bottom line is that transboundary management approaches must be selected on a case-by-case basis and ensure that they meet the needs of all riparian countries and, moreover, that water continues to be regarded as a nonmarketable human right and an international public good to be equitably allocated among stakeholders.

INTERNET GIS

Internet GIS refers to the use of the Internet as a means to exchange geospatial data, perform geographic information system (GIS) analysis, and visualize maps. Like many other new research fields, there is no general agreement on the term *Internet GIS*. Several alternative names have been adopted in the GIS community to represent similar concepts, such as online GIS, distributed geographic information (DGI), and Web-based GIS (or Web GIS). These different terms are similar, but they are not synonymous. For example, Web-based GIS refers to the use of Web browsers as the primary viewers/containers to conduct GIS tasks. However, some popular GIS applications, such as Google Earth, use their own browsers instead of relying on the default Web browsers. Therefore, Google Earth is an Internet GIS application, but it is not a Web-based GIS application. The term *Internet GIS* has a broader and more enduring meaning than *Web-based GIS*. It has the capacity to include other and new applications of GIS and the Internet.

The Internet is a modern information relay system that connects hundreds of thousands of telecommunication networks and creates an "internetworking" framework. The Internet framework includes local area networks (LAN), wide area networks (WAN), Internet Service Provider (ISP) networks, wireless communication networks, and intranets. Intranets are a subset of the Internet that use the same Internet Protocol and communication technologies within a closed environment, such as a company network, but with limited access and security enhancement.

Early Internet GIS prototypes appeared in the mid 1990s. Xerox Map Viewers, the Alexandria Digital Library project, and GRASSLinks are a few representative Internet GIS prototypes from

Figure 1 The three-tier architecture of the Internet GIS

Source: Author.

the early period. More recently, we have witnessed an explosion of interest in transforming GIS into the ubiquitous, distributed Internet GIS. These services are of value not only to various professionals using geospatial data in their daily work but also to the general public, to use spatial information for navigational and other purposes involving location-based data. There are Web sites powered by Internet GIS that allow people to check city zoning and parcel information, see where and what types of crimes are occurring in their neighborhoods, and learn when is the trash pickup day on their street.

GIS on the Internet presents a compelling and effective way of disseminating spatial information when compared with traditional paper maps or digital maps stored in centralized GIS or on CDs. Though the melding of GIS and the Internet seems a commonplace now, the idea was revolutionary in 1993. One of the earliest Internet GIS prototypes, called Xerox PARC Map Viewer, appeared on the World Wide Web that year. Developed at Xerox Corporation's Palo Alto Research Center, the Map Viewer allowed users to zoom in on a location on a picture-based map rendering of a globe and retrieve a map of the selected area from a geographic database. In 1994, two important organizations promoting

standardization in Internet GIS were established: the Open Geospatial Consortium (OGC) and the International Organization for Standardization (ISO) Technical Committee 211 (TC211). Specifications developed by OGC and ISO/TC211 for spatial data formats, data exchange, and data communication have become the basis for software interoperability and the ongoing development of Internet GIS. Along with the rapid development of Internet GIS, a new term, *geospatial cyberinfrastructure*, is used to represent the combination of distributed high-performance geospatial computing resources, georeferenced information, geoprocessing Web services, and geographic knowledge.

The Architecture of Internet GIS

Most Internet GIS today adopt a three-tier architecture for system implementation (Figure 1). The first tier, called the *client tier*, includes the user-side Web browser and user-resident Java applets/HTML documents. The user of Internet GIS interacts with the client tier via a graphical user interface (GUI) composed usually of a map and map navigation, spatial and attribute data query, and spatial analysis tools. The primary function of the client tier is to accept users' data requests and to

Type	Applications
Data sharing (exchanging)	• Online data warehouses (data archive) • Online data clearinghouse (metadata)
Information sharing (map sharing)	• Web-based map display • Navigation services
Knowledge sharing (spatial analysis and GIS modeling)	• Online GIS models • Web-based spatial analysis tools

Table 1 The three types of Internet GIS
Source: Author.

display the results of these requests. The second tier is the *middleware tier* and includes the Web server and the server connector (such as Servlet connectors or Active Server Pages [ASP] connectors) to bridge the communication between clients and the map servers. The third tier is the *data storage tier*, which includes the map server and the spatial database server. The three-tier software architecture of Web-based GIS provides customizable functions for different mapping applications and scalable implementations for different volumes of use and, correspondingly, different hardware configurations.

Three Types of Internet GIS

There are many different Internet GIS applications, ranging from data clearinghouses, Web mapping, data portals, Web-based decision support systems, and GPS tracking to digital Earth viewers and virtual globes. In general, we can categorize the various Internet GIS services into three types: (1) data sharing, (2) information sharing, and (3) knowledge sharing (Table 1).

Data sharing combines the functions of online data archive and data search services. Two typical applications are online data warehouses (or data archive centers) and online data clearinghouses. An online data warehouse is used for archiving, accessing, and downloading both GIS databases and/or remotely sensed imagery. A Web-based data clearinghouse can help users search and index the contents of metadata and then access the actual data through the descriptions of metadata.

The second type of Internet GIS services involves information sharing and map sharing. Multiple interactive map servers and mobile navigation services are the typical applications. Web-based mapping functions include the display, zooming in or out, and query of spatial information. The major requirement of information-sharing services is to provide effective Web-based display mechanisms and client-server communication protocol.

The third type of Internet GIS focuses on the sharing of knowledge and GIS models. This is the most challenging task for the development of Internet GIS, and only a few applications are available today. The goal is to provide online GIS modeling and spatial analysis functions without running GIS engines or software packages locally. Some Internet GIS applications use Java or other distributed component technologies (such as .NET or Web services) to develop online GIS model functions. The implementation of these Web-based software components can provide ubiquitous access for all different types of GIS applications.

New Directions of Internet GIS

There are many Internet GIS applications using Web services and application development interfaces (APIs) for Web mapping or geocoding functions. Web services are interoperable and self-describing applications that can communicate with each other. Many software companies, such as ESRI, Google, Yahoo, and Microsoft, have developed several Web service applications and

Web Map APIs. Web application developers can use and combine these APIs and Web services into Web-based GIS applications for providing basic mapping and GIS functions. It is likely that some of today's users of desktop GIS software packages will use in the future exclusively Web-based GIS services and that the user base of desktop GIS will shrink. The advantages of Web services include easy integration with other Web GIS applications and the low cost of software and hardware compared with the cost of software and hardware required by traditional GIS systems.

Another exciting new direction of Internet GIS is the development of three-dimensional (3D) virtual globes such as Google Earth, Microsoft Virtual Earth, and ESRI's ArcGIS Explorer. They represent an evolution in technology, but to people outside the GIS community, it's a revolution in the way people understand geography and the world around them. The virtual globes provide an appealing way to convey to people spatial concepts and geographic information.

INTEROPERABILITY AND SPATIAL DATA STANDARDS

The International Organization for Standardization (ISO, 1993) defines interoperability as “the capacity to communicate, execute programs, or transfer data among various functional units in a manner that requires the user to have little or no knowledge of the unique characteristics of those units.” In the context of geographic information, the functional units are geographic information systems (GIS) or Web services. The communication between these units comprises transfer of spatial data as well as querying and execution of remote services. In this respect, two types of interoperability can be distinguished: (1) *syntactic* interoperability refers to format of the transferred data, that is, compliance with spatial data standards, and (2) *semantic* interoperability builds on syntactic interoperability and refers to the accurate preservation and interpretation of the *meaning* of the transferred information. The focus of this entry is on syntactic interoperability and the standards enabling heterogeneous GIS and services to interoperate. Note that the kind of interoperability discussed here relies on lower-level *technical* interoperability, where established standards guarantee that a CD can be read in every CD drive, computers can communicate through telephone wires, electric devices can be operated on every power outlet, and so forth.

Interoperability is a key requirement for the seamless exchange of spatial data between users and organizations employing different GIS and Web services. On a broader scale, the standards enabling interoperability are the cornerstones of spatial data infrastructure (SDI). Without agreements on the formats of the transferred spatial data and the interfaces for accessing the corresponding Web services, mutual data exchange between different GIS would at least require manual transformation of the data or even be impossible altogether. The most important organizations that develop such standards for the geospatial domain are the Open Geospatial Consortium (OGC) and the ISO Technical Committee 211 (ISO/TC211), responsible for geographic information/geomatics. Both organizations have a working agreement, resulting in a frequent mutual adaptation of standards.

Data Interoperability

Before the Web became a common platform for the exchange of geodata, interoperability mainly concerned the exchange of spatial data between different desktop GIS workstations on different kinds of media. Early exchange formats for spatial information such as ESRI's shape file format were de facto standards stemming from the widespread use of their ArcGIS and ArcView software. To enter the market, other software vendors had to support these proprietary formats, which are still common today. Besides specialized GIS formats, vector data were often exchanged in file formats originally developed for computer-aided design (CAD) software. Raster data were (and still are) mostly exchanged in standard graphics file formats such as JPEG, PNG, or (georeferenced) TIFF.

In a more contemporary sense, interoperability is usually reached by standards that are established by industrial consortia or independent standardization organizations. One such vendor-neutral standard for geographic features that is commonly used today is the Geography Markup Language (GML) introduced by the OGC. GML is an eXtensible Markup Language (XML) encoding for the transport and storage of geodata that can be tailored to specific applications via application schemas. Application schemas define the specific feature types and property types that are relevant for a given domain based on the GML meta schema. Due to the complexity of GML caused by this multipurpose design, numerous developers favored the simpler Keyhole Markup Language (KML), especially for nonprofessional or Web 2.0 mash-ups. KML was originally a proprietary format used in Google Earth and has been put under control of the OGC in 2007. It became an open OGC standard in 2008.

Besides the actual data, their descriptions in metadata must also be standardized to allow interoperable data discovery in catalog services. This standardization refers to the metadata encoding as well as the minimum set of mandatory properties, allowing for metadata profiles for different applications. The ISO 19115 specification (part of the ISO 191xx set of standards for geographic information) provides such a standard specifically developed for metadata on geodata.

It comprises more than 400 different elements, of which a small subset is compulsory. Besides ISO 19115, the Dublin core metadata standard is also commonly used for spatial information, although it is a general-purpose standard and has not been developed specifically for geodata.

Web Service Interoperability

Web services enable loosely coupled service-oriented architectures that provide Internet-based access to spatial data stored in remote databases. They allow for the execution of distributed geoprocessing functionality such as the online computation of standard GIS operations. In addition to standards for the formatting of the transferred data, Web services require standardized interfaces for communication with these services. The OGC has developed a number of standards for geospatial Web services, with the most widely adapted being the Web Map Service (WMS) and Web Feature Service (WFS) specifications for the retrieval of raster and vector data, respectively. Further specifications cover advanced functionality such as geodata processing (WPS), sensor observation (SOS), or location services (OpenLS; see Percivall, 2003, for a complete overview). OGC specifications define Web service interfaces by specifying the formats for requests and responses. This implementation-independent approach allows existing proprietary Web services to be subsequently equipped with an additional OGC compliant interface. Such a mapping is especially important for the integration of existing services into SDIs and follows an approach that has proven useful on the technical level: For a user, it is sufficient to know the interface, such as a power outlet or a WMS interface, and the corresponding interactions. It is then irrelevant how the electric power is generated or how a map tile is composed to make use of the interface. At the same time, this approach allows developers great latitude in the actual implementation of the services.

INTERVIEWING

Interviewing is one of the most common social science research methods; it is used by a wide array of human geographers to gather information about people and particularly their views about their world and how they feel they and others fit within it. Interview “data” are typically obtained through verbal communication between the researcher and participant: face-to-face, over the telephone, and, occasionally yet increasingly, over the Internet as textual chat or Voice Over Internet Protocol (VoIP). The term *interview* is used to describe a wide range of techniques in both popular culture and academia. Though it is sometimes used to describe face-to-face, closed-ended, survey questionnaires that are filled out by the researcher, *interview* more commonly describes the far less structured qualitative technique.

The interview as a modern-day qualitative social science method developed alongside participant observation and other so-called field methods, particularly within the Chicago School of Sociology and their now-famous urban ethnographies of the 1920s, 1930s, and beyond. Among the prominent influences at this time were the work of George Herbert Mead and the philosophy of pragmatism. Both were later interpreted by Herbert Blumer, who coined the term *symbolic interactionism* in an attempt to simplify

the philosophical underpinnings of the interview method. The emphasis of symbolic interactionism is that it is mainly through interaction between humans that social meaning and action can be fully understood. This approach is consistent with the works of several German philosophers and the philosophy of phenomenology, which predates the Chicago School. Phenomenology in particular was opposed to the strict requirements of objectivity in highly structured positivist social science. Yet phenomenology also forms the philosophical basis for reflection, or reflexivity, as a central aspect of qualitative interviewing. The interviewer is expected not only to reflect on the conscious intentions of the research participants but also on his or her own intentions as well as the influence of his or her social position within the interview process.

In terms of practical advantage over more structured methods, qualitative interviews are used in three interrelated types of research: (1) topics that have not yet been studied extensively; (2) exploratory research with groups of people who are hard to reach, such as the homeless; and (3) studies that seek to understand personal or sensitive topics or that require participant reflection. In the case of new topics, and by virtue of the flexible nature of interviews, they provide the opportunity to develop new theoretical concepts rather than simply test existing ones. In relation to the latter two types of research, because the interview is more personable than questionnaires, interviews ideally allow the researcher and the participant to develop a positive rapport or social trust. This helps get at the deeper meanings that such research requires.

Qualitative interviewing is meant to be more conversational than questionnaire-based survey interviewing. Qualitative interviewing involves the concept of the *researcher as instrument*, whereby the researcher, as a social-interpretive being, is considered very central to the interview and interpretive processes. Thus, the researcher's ability to react to the social situations within the interview is not nearly as constricted in the name of objectivity as it would be in the case of survey questionnaires. That said, the researcher often withholds at least some of his or her own personal views—a source of some debate among interview practitioners.

It is the subjective meanings of the participants that are the focus of the qualitative interview, and somewhat paradoxically, these meanings themselves are at least partially socially constructed by the interview process itself. That is, interviews do not entirely tap into preexisting understandings; the interview conversation helps articulate some meanings that might otherwise be left veiled by the participant's need to get on with daily life. By responding to participants in ways that more closely approximate everyday social life, the qualitative interviewer can be more empathetic, which ideally contributes to a positive rapport. Furthermore, the researcher as instrument can simultaneously interview and observe such that the interview process is conducted holistically. Thus, the presentation of self is important in the interview since interview participants do indeed act in response to how the researcher presents himself or herself—for example, as an academic, student, activist, feminist, Muslim, wealthy, or politically left of center. In the case of face-to-face interviews, the researcher as instrument also entails attention to the physical presentation of self in terms of dress, mannerisms, and even the setup of the interview location since these all can both enable and constrain what may be learned through interviewing.

All types of qualitative interviews are meant to be conversational but vary along a continuum from structured to unstructured. Interviews typically involve a list of topics to be covered—an interview guide or interview schedule. For example, semistructured interviews may involve a detailed list of topics and probes in the guide; yet the researcher may nevertheless retain the flexibility to cover the topics out of order or pursue topics raised by the participant. Not only does this allow the interview to be more conversational, it surrenders some control over the path of the conversation to the participant.

Interview “data” are commonly interpreted as text, though the interview itself is often audio recorded and subsequently transcribed into text. Otherwise, field notes taken during the interview are the substance of interpretation. The choice or recording strategy may thus involve trade-offs between the intrusiveness of the recording method, accuracy, and the comfort level of the participant. In all cases of data recording, reflections on the

interview situation (e.g., reasons for guarded responses) are recorded during or soon after the actual conversation. Thus, interpretation occurs throughout the interview process from topic inception through write-up.

Despite the researcher's desire to share power over the form and content of the conversation, interviews, like other qualitative methods, involve some serious ethical challenges. This goes beyond the more straightforward issue of obtaining informed consent, which allows participants to withdraw from the research without negative impacts. However, since much interview work is conducted with disadvantaged groups in society, there are more subtle ethical considerations over issues of power, control, and the uses to which data are put. In most instances, the researcher has the most control over the content and ultimate trajectory of interviews and particularly what is interpreted from them. This can create tensions between interpretations that are intended for more academic audiences and those that serve to more directly address the problems of the group(s) being studied. Such issues are most keenly debated among feminist and participatory action researchers and between them and other types of less action-oriented interview practitioners.

INVASION AND SUCCESSION

Invasion and succession are the establishment of one or more species in an area previously uninhabited by those species and the subsequent progression of the ecological community's species composition in that area through time. As ecological terms, *invasion* and *succession* are usually discussed independently from each other. Invasion, in an ecological sense, occurs when a species, usually an exotic or nonindigenous species, is introduced to an area and is able to persist in that area, often at the expense of native species. Ecological succession refers to the changes in species composition in an area over time. Succession is typically conceptualized as a progression of species compositions in an area that eventually achieves a climax stage, which remains dominant in an area until a disturbance in that area (e.g., a fire or a strong storm) resets the species composition to an earlier stage of succession. This is an example of secondary succession. Primary succession occurs when ecological communities form in an area that had no previous communities or abiotic habitat development. Ecological community development on land just formed by a volcano or newly uncovered by a landslide is an example of primary succession.

The invasion of an ecological community by an exotic species is typically viewed as a negative process. The invading species can potentially disrupt the interspecies ecological dynamics of the native community. This can result in the loss of native species in an area. The lack of natural predators of the invading species can result in their unchecked population growth. If the invading species are pathogenic to the native species, the natural defenses of the native species may not be able to resist the invading species. These

factors can result in catastrophic ecological disruptions to native communities.

Combining the ecological processes of invasion and succession provides an integrative view of the changes that ecological communities experience through time. This has become more important as modern economic globalization continues to expand linkages between different places in the world. These links are often in the form of major physical transportation agents, such as boats, airplanes, and trains, which have transported many species to areas beyond their native ranges. The introduction of these species to new areas provides them with invasion opportunities. Once these invasive species become established in an area, they will compete with native species for niche space within the stages of succession that the area experiences. Successful invasive species eventually find a stable niche within a native community and in time are described as nonnative elements of the community.

ISARD, WALTER (1919–)

Walter Isard is the father of the discipline of Regional science. Often characterized as an “economic geographer,” his work is much broader, also encompassing urban and regional planning, operations research, transportation, applied engineering, political science, sociology, and ecology.

The focus of regional science is on space and location, and it treats a region (any subnational entity not necessarily defined by political boundaries) as an organic whole.

Walter Isard was born in Philadelphia in 1919. He graduated from Temple University with honors in 1939 and then studied at Harvard and the University of Chicago. While working for the National Resource Planning Board during World War II, he completed his dissertation on building cycles and transportation development and received his PhD from Harvard in 1945. Isard returned to Harvard that year as a research associate and an instructor, and he designed the first course in location theory there. By the late 1940s, he helped form a small group of economists, which eventually expanded in number and breadth to include people from related disciplines, culminating in the founding of the Regional Science Association in 1954. Isard moved to the department of city and regional planning at Massachusetts Institute of Technology in 1953. In 1956, he was invited to join the economics department at the University of Pennsylvania but insisted on forming his own department of regional science, which he served as chair until 1975. He initiated the *Journal of Regional Science* in 1958 and later founded the journals *Regional Science and Urban Economics* and *The International Regional Science Review* in the early 1970s.

The second discipline founded by Isard was Peace Science, a rigorous, interdisciplinary inquiry into the topic. In 1963, he helped form what is now the Peace Science Society, and in 2006, he established the journal *Peace Economics, Peace Science and Public Policy*.

Isard's key initial contribution was the reformulation of the work of European location theorists, such as von Thünen, Alfred Weber, Walter Christaller, and August Lösch, into neoclassical microeconomics. Although there were several scholars who worked on this topic in the United States previously, Isard's *Location and Space Economy* provided a comprehensive, unified framework. Prior to this, economics lacked a formal spatial dimension and treated the economy as if it operated on the head of a pin. Interestingly, the neoclassical core of regional science has caused a distancing between this discipline and human geography, as the latter places an increased emphasis on social theory and political economy.

Isard published several other influential books over the next 20 years, including *Industrial Complex Analysis and Regional Development* in 1959 (an early foray into agglomeration economies); *Methods of Regional Analysis* in 1960 (instruction on a broad spectrum of analytical and practical tools, including input-output analysis and various types of mathematical programming); *General Theory: Social, Political, Economic and Regional* in 1963 (to further unify various aspects of spatial analysis, economics, and related disciplines); *Ecological Economic Analysis for Regional Development* in 1972 (a precursor of modern ecological economics); and the textbook *Introduction to Regional Science* in 1972.

In 1977, Isard moved to Cornell University, where he was given appointments in the department of economics and city and regional planning, as well as the regional science program and peace science program, which he established (he had held a visiting appointment at Cornell since 1971). Isard is now professor emeritus at Cornell and remains active in several fields at the time of this writing.

Isard was the mentor of many notable scholars at the University of Pennsylvania, including William Alonso, Eugene Solensky, and David Boyce. His students in economics at Cornell included Luc Anselin and this author. He has been listed among the ranks of leading economists, and his contributions to other disciplines, especially geography, are well acknowledged.

ISLAND BIOGEOGRAPHY

Islands have always had a great influence on the natural sciences, far out of proportion to the tiny fraction of Earth's surface that they cover. The reason for this is straightforward: Islands and other insular habitats, such as lakes, caves, springs, and mountaintops replicate natural experiments. Island biogeography is a field within biogeography that attempts to describe and understand the innumerable patterns in the distribution of species arising from these natural experiments.

Island Types

Islands can be divided into two broad types: (1) *true islands*, land wholly surrounded by water, and (2) *habitat islands*, other forms of insular habitat, that is, discrete patches of habitat surrounded by strongly contrasting (hostile) habitats.

In terms of geology, geography, and biology, true islands can be subdivided into two types:

Oceanic Islands. These are islands formed over oceanic plates; they are of volcanic origin (although sometimes their subaerial parts are in part or wholly composed of sedimentary, and especially coral, formation as the volcanic core has sunk) and have never been connected to continental landmasses, from which they are separated by deep sea (e.g., Azores, Canaries, Hawaii, Iceland, Tristan da Cunha). They generally lack indigenous land mammals and amphibians but typically have a fair number of bird species and insects and usually some reptiles.

Continental Islands. These islands are located on the continental shelf. Typically, many of these islands have been connected to the mainland during the Quaternary ice ages (e.g., Britain, New Guinea, Sri Lanka, Sumatra, Trinidad). They are rarely remote and always contain some land mammals and amphibians, as well as representatives of the other classes and orders in considerable variety.

Continental Fragments. These are islands that formed on ancient fragments of continental rock stranded out in the oceans by plate tectonic processes, although by their location they might otherwise pass for oceanic islands (e.g., Crete, Cuba, Madagascar, New Zealand, Seychelles). Typically, they exhibit high endemism and relictualism.

The Significance of Islands

The biotas of islands, especially of oceanic islands, characteristically differ from continental biotas in four main ways: They are relatively impoverished, unsaturated, and disharmonic, and they harbor a disproportionately high number of endemic species. Considering New Guinea as the largest island, islands constitute only 3% of the total landmass of the Earth, while more than 15% of plant, land snail, and bird species are restricted to islands. In the case of higher plants, more than 13% of the world's species are endemic to just 13 islands/archipelagoes. The high endemism of islands means that island species are crucially important to global biodiversity. The first three traits mentioned above are often considered as being largely responsible for island species and communities being particularly fragile when exposed to external pressures.

The ecosystems of islands (coastal, marine, and inland) provide valuable services to more than 500 million people—namely, food, tools, industry, medicine, transport, and waste disposal. With increasing human population pressures through high migration and reproductive rates, island systems face several serious issues both in the immediate and in the near future. The natural land cover of island systems has changed drastically under the pressure of growing human populations and the consequent exploitation of the landmass (e.g., the Azores have lost more than 90% of their original native forest during the five centuries of human occupation). On some islands, the impact has exceeded critical thresholds, particularly along the coastal periphery. Anthropogenic changes range from deforestation for cropland to urbanization and the abandonment of degraded land. All these have immediate repercussions in destruction of the remaining habitat and loss of biodiversity.

In the current age of mass anthropogenic extinctions, islands qualify as “hot spots,” combining the attributes of high levels of unique biodiversity, recent species extinctions, and likely future species losses (i.e., they have a high unpaid extinction debt). A disproportionate fraction of all endangered and recently extinct species are island species. The majority of recorded species extinctions since circa AD 1600 have occurred on islands

Group	Islands	Continents	Oceans	Total	% Insular
Mammals	51	30	4	85	60
Birds	92	21	0	113	81
Reptiles	20	1	0	21	95
Molluscs	151	40	0	191	79
Insects	51	10	0	61	84
Plants	139	245	0	384	36
Total	504	347	4	855	59

Table 1 Summaries of known extinctions from islands, continents, and oceans since circa AD 1600

Source: Whittaker, R., & Fernández-Palacios, J. (2007). *Island biogeography: Ecology, evolution, and conservation* (2nd ed., Table 11.2). Oxford, UK: Oxford University Press. Reprinted with permission.

(Table 1). Approximately 70% of recorded extinctions in five animal groups (mammals, birds, amphibians, reptiles, and land snails) have been island species. Avian extinctions are overwhelmingly concentrated on oceanic islands, especially on Hawaii and New Zealand, with very few elsewhere. With few exceptions, oceanic island avi-faunas have lost a significant proportion of their endemic species over the past 1,000 years.

Island Theories

Islands provide replicated series of more or less self-contained systems that can serve as nature’s “laboratories.” They have thus featured predominantly in the development and testing of theories. The equilibrium theory of island biogeography (ETIB) is arguably the single most influential theory in the study of geographic patterns of diversity. Its influence is marked not just by the research it has motivated but also by the theories and applications it has spawned/influenced (e.g., species-energy theory, metapopulation theory, island assembly theory, neutral theory, and stochastic niche theory).

The dynamic, equilibrium model of ETIB postulates that the number of species of a given taxon found on an island will be the product of opposing forces leading consecutively to the gain and loss of species and resulting in a continual turnover of the species present on each island through time. This is captured in graphical mode in Figure 1: The immigration rate declines exponentially and the extinction rate rises exponentially as an initially empty island fills up toward

its equilibrium richness value (shown by the intersection). The immigration rate curve flattens with increasing isolation, and the extinction rate with increasing area, thereby generating a family of curves providing unique combinations of richness and turnover for each combination of area and isolation.

Although ETIB has proved more difficult to test than first hoped, as a heuristic device it has been and continues to be extremely important in organizing thought on patterns of species diversity and in providing a framework against which to consider other models of diversity. Modifications and improvements on the basic ETIB model can help provide a more robust framework for evaluating and predicting patterns of species diversity, although some contend that sharper departures from this theoretical framework are needed.

One key element in any general model is to more explicitly recognize the important role that adaptive radiation plays in increasing species diversity on islands. This is mentioned but not fully developed in the ETIB. Recently, it has been proposed that for oceanic islands, it is important to consider island “ontogeny,” that is, the life history of an island itself, for describing the interplay of immigration, extinction, and speciation in establishing species richness. A volcanic island’s size, topographic complexity, ability to support life, and potentially its likelihood of promoting speciation change over geological time as the island forms out of the ocean, grows larger and higher, and then begins to shrink, lose elevation, and eventually become eroded below the surface

Figure 1 The equilibrium model of island biogeography

Source: Adapted from MacArthur, R., & Wilson, E. (1967). *The theory of island biogeography* (Figure 8, p. 22). Princeton, NJ: Princeton University Press.

Notes: An equilibrium number of species (S) is set by two opposing processes: immigration (I) and extinction (E). The rate of immigration decreases and the rate of extinction increases with increasing richness; the rate of immigration reaches zero when the entire pool (P) of potentially immigrating species have arrived. Immigration rates on islands far (I far) from the source pool are expected to be lower than those on near (I near) islands. Extinction rates are expected to be higher on small (E small) islands than on large (E large) islands. Hence, different equilibrium numbers of species are established based on the area and the isolation of the islands ($S_{F,S}$; $S_{F,L}$; $S_{N,S}$; $S_{N,L}$). Differences in rates of species turnover (T) are expected to vary with the combination of immigration and extinction rates that characterize any given island ($T_{F,L}$; $T_{F,S}$).

of the sea (Figure 2). This and other contributions can offer the foundation for an expanded theory of island biogeography, unifying ecological and evolutionary biogeography.

Island Theory and Conservation Biogeography

Within a few years of the publication of the ETIB, its application to the field of conservation biology

was being vigorously debated. This was based on the realization that reserves and national parks formed islands, that is, habitat islands, inside human-altered landscapes (habitat fragmentation), and that these reserves could lose species as they “relaxed toward equilibrium,” achieving a new lower equilibrium number.

Based mainly on island biogeography theory, a theoretical framework for fragmentation research has been established, seeking to derive

Figure 2 Graphical representation of the key rates and properties of the general dynamic model (GDM) of oceanic island biogeography

Source: Whittaker, R., Triantis, K., & Ladle, R. (2008). A general dynamic theory of oceanic island biogeography. *Journal of Biogeography*, 35, 977–994 (Figure 4, p. 981).

Note: The postulated relationships between the biological characteristics and the ontogeny of a single island, where for Key rates, I is the immigration rate, S is the speciation rate, and E is the extinction rate (each rate referring to the number of species per unit time) and for Species number, K is the potential carrying capacity and R is the realized species richness. For islands showing sudden extensive loss of territory due to landslips (as suggested by the kinks in the K and R curves), the extinction rate curve would require modification. Island building being typically much more rapid than decline, time should be considered as some form of log.

key reserve network design principles (Figure 3). One of the most prominent contributions was the so-called SLOSS debate, which posed the question “Given the opportunity to put a fixed percentage of land into conservation use, is it better to opt for a single large or several small reserves?” Unfortunately, the ETIB does not tell us with any precision how species should be distributed across a system of fragments, and this is crucial to the issue of whether it is better to

advocate one very large reserve or several smaller ones of the same total area.

In general, island theory provides a basic conceptual model for understanding habitat fragmentation. However, apart from a number of broad generalizations, the relevance of island theory for understanding fragmented ecosystems has proved to be limited, so far. Recently, a new subdiscipline has emerged, conservation biogeography, which is the “application of biogeographical principles,

Worse		Better	
a)	Small reserve 	 Large reserve	
b)	Fragmented reserve 	 Unfragmental reserve	
c)	Higher edge effects  500 ha reserve	500 ha reserve  200 ha core Lower edge effects	
d)	Isolated reserves 	 Increased connectivity (corridors)	
e)	Isolated reserves 	 Increased connectivity (stepping stones)	
f)	Partial protection 	 Complete protection	
g)	Uniform habitat 	 Increased habitat diversity	
h)	Local perspective 	 Regional perspective	
i)	Humans excluded 	 Human integration (buffer zones)

London: Routledge.

theories, and analyses, being those concerned with the distributional dynamics of taxa individually and collectively, to problems concerning the conservation of biodiversity.” Within the context of conservation biogeography, we can reevaluate the theoretical frameworks provided by island theory, their relevance to particular systems, and their wider and important role in helping us understand the sorts of effects that might be operative in real-world contexts.

ISLANDS, SMALL

While one can envision at a global scale that all land is an island between the Earth's vast oceans and seas, relatively small islands dot much of the globe, many of which can easily be traversed by foot in only a few hours. An accurate count of small islands is difficult, as the number changes with tidal conditions and minimum-size requirements. Most are so tiny as to be uninhabited, and a high percentage of them have been termed internationally by organizations such as the United Nations as small-island developing states (SIDS) since 1994. However, there is no formally recognized definition of “small islands.” Approximately, 50 SIDS are located across the Pacific, Atlantic, and Indian Oceans. Small islands tend to be more environmentally fragile, insular, and remote than large islands (e.g., Madagascar, Borneo, New Guinea, or even Greenland) and thus deserve their own entry.

Small islands may be divided into high islands and low islands, and are important to geography for many reasons. For example, there are unique physical processes that form high and low islands: Biodiversity, and endemism in particular, is remarkably high on them. Small islands are likely to be early victims of climate change as reefs bleach, sea-level rises, and storms intensify, which, given their tiny carbon footprint, makes their condition an environmental justice issue. Of course, their relative remoteness results in great social and marine and terrestrial biophysical data gaps, and this too should interest geographers.

High Islands

One approach to classifying small islands is based on their formation. High islands such as the Hawaiian Islands, Bora Bora, and Pohnpei are created by volcanic action, often through tectonic plates moving over fixed hot spots of pressurized magma in the upper mantle. This often results in a dominant conical form with basaltic geology and high relief (see high island photo).

High-island topography causes orographic lifting of moisture-laden clouds fed by the surrounding ocean, producing remarkable amounts

The high island of Tonowas in Chuuk Lagoon, Chuuk State, Federated States of Micronesia

Source: Dr. William James Smith Jr.

of rainfall. Some of the wettest places on Earth are found on small high islands (e.g., approximately 1,200 millimeters per year on Kauai in Hawaii). This high-island relief, together with being spread about large spaces and in great isolation, also results in a tremendous degree of habitat diversity. In the tropical small islands, streams, terrestrial forests, mangrove forests, grasslands, and fringing coral reefs produce habitat for a large number of endangered or endemic species. Charles Darwin's theory of evolution and E. O. Wilson's theory of island biogeography are two scientific cornerstones relating to understanding island biodiversity.

Taking the Micronesia region of the Pacific Ocean as an example, which includes the Republic of the Marshall Islands, Territory of Guam, Commonwealth of the Northern Mariana Islands, Republic of Palau, and Federated States of Micronesia (FSM), all the nations have taken the "Micronesia Challenge" (MC), a commitment to biodiversity conservation, launched in Curitiba, Brazil, in 2006, during the eighth meeting of the Conference of the Parties to the Convention on Biological Diversity. The jurisdictions involved in the MC have committed at least 30% of their marine areas and 20% of their terrestrial areas to be under effective management by 2020. It is estimated that 30% of the world's

coral reefs are significantly damaged and the extent of the damage will double by the year 2030 if no conservation measures are undertaken. Notably, approximately half of the world's plant and animal species that have become extinct are island species. The jurisdictional area associated with the MC represents 10% of the Pacific Ocean, and when implemented, the MC will protect 10% of the world's reef area and 462 coral species, which represent 58% of all known corals. The then-FSM vice-president, Killion, described the initiative as a regional framework that is aimed at poising the Micronesian island governments toward achieving the targets and objectives set forth in the Convention on Biological Diversity and the Millennium Development Goals. Micronesia is a biodiversity "hot spot."

Low Islands and Atoll Structures

In contrast to high islands, low islands are created by deposition of coral rubble and sand on shallow reefs. These shallow reefs form when volcanic islands sink, either through subsidence of the tectonic plate as it moves toward subduction or through compaction as the underlying rocks cool and shrink. As the volcanic cores sink below

Figure 1 Chuuk Lagoon from satellite imagery, Chuuk State, Federated States of Micronesia

Source: Created by Dr. William James Smith Jr. from LSat.

Note: Coral appears in light blue.

the ocean surface, coral reefs grow upward, maintaining a relatively constant position relative to the surface. Eventually, the volcanic core is completely buried in coral growth, and an atoll, a roughly circular collection of islets around a shallow lagoon, forms. The size of each islet is typically less than 5 square kilometers, with maximum elevation less than 5 meters. Soils are nearly entirely composed of coral sand, with a very shallow freshwater lens. Figure 1 shows Chuuk Lagoon, the world's largest "almost atoll"—note the high islands in the middle and the remaining low islands. Note in the low islands photograph the development of major islands in corners and

the protection from wave action the reef provides for the interior of the lagoon, making fishing and other activities safer. Freshwater lenses tend to be thicker on the inside of the structure.

Saltwater intrusion poses challenges for both vegetation and human settlement on low islands. Low islands produce limited habitat and species diversity. There are few perennial (or even ephemeral) streams; vegetation is predominately herbaceous strand or strand forest; and though mangroves are possible, they are not nearly as developed as on high islands. Climatic diversity is assumed to be nonexistent on atolls because of the relative lack of topographic variation on low islands. Low islands

A string of low islands in the Marshall Islands

Source: Dr. William James Smith Jr.

also typically have smaller populations. Given the projections for climate change, low islands may serve as the “canary in the coalmine” for global climate change. Islands need not be covered permanently with water to be uninhabitable, as unsafe or saline conditions from washover and sea-level rise may make inhabiting such islands impossible. This will create a loss of cultural as well as biophysical diversity, which is unfortunate given that small-island populations are not industrialized and produce negligible greenhouse gases, while their vegetation and large national marine areas serve as significant global carbon sinks.

ISOPLETH MAPS

Isopleth maps are a type of thematic map used to display and model observations of phenomena with a continuous distribution by representing the values as a third-dimensional surface draped over the area. This common mapping technique is appropriate for diverse topics. Similar terms, mapping techniques, value interpretation, and specific isopleths, especially contours, are discussed.

Broadly called isoline maps, a distinction is sometimes made between isometric and isoplethic mapping, wherein isometric maps display real values such as rainfall amounts and isoplethic maps display calculated values such as population density. The terms *isarithm* and *isogram* are generally synonymous. *Iso* means “equal,” and *pleth* refers to “quantity.”

If something can be measured or generalized at any location, such as air temperature, then potentially, isopleth mapping can be used to show the spatial patterns. Observations cannot be made everywhere, so isopleth maps are constructed by interpolation from measurements at specified locations or associated calculations.

Isopleth maps use lines of equal value to portray patterns. These isopleths or isolines are plotted by assuming an even rate of change between the locations of known values. An isopleth interval identifies the difference in value between adjacent isopleths. The lines drawn are multiples of this isopleth interval. Smaller intervals mean more lines will be shown and more detail will be interpolated. This does not enhance accuracy. Isopleths enclose areas of either higher or lower values. They can neither cross nor split apart, because the line can have only one value. More closely spaced isopleths indicate more rapidly changing values.

Isopleth maps are read by identifying the value of the line through the point or the value of the adjacent higher and lower lines. For a point not on a line, a range is indicated. A value can be interpolated from the relative location between the lines, but the reader should remember the original generalization process used to produce the maps and not infer excessive detail.

The most difficult aspect of reading isopleths involves identifying the continuity between the

Figure 1 Continuity of values on isopleth maps

Source: Author.

high and low centers. A low center or a depression is an area completely surrounded by higher values. The primary skill involves maintaining the value trend. Any reverse in the trend is indicated by a repeated line value. If the value of the lines is increasing in the direction of a high center and a low center is encountered, the line value most recently passed will be repeated, indicating the change in the trend. However, if the trend is going down from a high center into a depression, the values do not repeat (Figure 1). Shaded isoline maps color the areas between the lines for clarification.

A contour map shows elevation of the land surface and is a specialized isopleth map. These differ by the inclusion of hachures, small tic marks pointing downslope, added to the lines in the low centers. The same interpretation skills are applied to read the values. The first hachured contour line has the same value as the lower adjacent unhachured line.

<i>Name for Isoline</i>	<i>Connects Equal</i>
Geoisotherm	Underground temperatures
Isallobars	Changes in air pressure through time
Isobar	Barometric or atmospheric pressures
Isobaths	Water depths
Isobathytherm	Water depths with equal temperatures
Isobrunr	Occurrences of thunderstorms
Isoceraunic	Numbers of thunderstorms
Isochalaz	Frequencies of hail storms
Isochasm	Aurora recurrences
Isochein	Mean winter temperatures
Isochrones	Elapsed times, such as for travel
Isocost	Production costs
Isodapane	Costs of travel
Isodemic	Population densities
Isodose	Intensities of radiation
Isodrosotherm	Dew point temperatures
Isogonal	Magnetic declinations
Isohaline	Ocean salinities
Isohel	Amounts of solar radiation
Isohume	Humidities
Isohyets	Precipitation
Isohypse	Elevations
Isoneph	Cloud cover
Isopach	Thicknesses of stratigraphic unit or group
Isophene	Times of flowering plants
Isophote	Brightness or illumination
Isoplankt	Plankton or plankton species
Isoquant	Production quantities
Isoseismal	Earthquake intensities
Isoshear	Vertical wind shear strength
Isotac	Dates of thawing each spring
Isotach	Wind speeds
Isothere	Mean summer temperatures
Isotherm	Temperatures
Isotim	Transportation costs from raw material source

Table 1 Names of selected isolines

Source: Author.

Specialized names are applied for different data. Lines that connect points of equal temperature are isotherms, and isobars are lines that show equal atmospheric or barometric pressure (Table 1). The diversity of line types demonstrates the versatility and usefulness of isopleth mapping.

**JACKSON, JOHN
BRINCKERHOFF
(1909–1996)**

Although not officially a geographer, J. B. Jackson was widely revered as an insightful and prolific analyst of cultural landscapes. Dominating mid-20th-century scholarship on this topic, he was claimed by several disciplines, including landscape architecture, geography, history, literature, and American studies.

Born in France, Jackson spent much of his early life in Europe, including school in Switzerland, as well as the Washington, D.C., area. Later, he went for 1 year to the Experimental College of the University of Wisconsin and then to Harvard, where he completed his BA in 1932. In the military as an intelligence officer during World War II, he acquired cartographic skills and a mastery of aerial photo interpretation, which likely fueled his interest in landscape formation and meaning. Jackson's understanding of cultural landscapes was derived from several sources, such as the influential French geographer Paul Vidal de la Blache and the American Carl Sauer, whom he met in Berkeley. He taught numerous courses at Harvard and at the University of California at Berkeley and was widely influential pedagogically. His later life was largely spent in New Mexico.

In 1951, Jackson launched the magazine *Landscape: The Human Geography of the Southwest*,

which he edited until 1968. Its influence was far greater than its narrow label might suggest. Numerous well-known geographers contributed to it, as did Jackson himself, sometimes using pseudonyms. Although its subscription base was small, it played a significant role in popularizing views of vernacular landscapes, particularly illustrating the human role in imposing meaning on places that might otherwise escape attention. When most academics disdained the vernacular, he celebrated the ordinary and everyday. He focused on American popular landscapes, drawing on his extensive travels across the United States, including mundane phenomena such as parking lots, bus stations, front lawns, roadside restaurants, and strip malls, adapting cultural geography to the age of the automobile. Roads and highways merited special focus as linkages among places and communities. His works blended diverse elements of landscape architecture, historical preservation, and urban planning. Through architecture, he held, people organized space and materialized the aesthetic. His insights were peppered with a disdain for modernism and a love of the baroque, although his work concentrated on the ordinary rather than the unusual or spectacular. He emphasized landscapes as largely unplanned, contingent, often ambiguous, and usually improvised entities. His writings helped move the study of cultural landscapes from its previous focus on relic rural places to contemporary urban ones, and they formed the foundation for the notion that landscapes could be read or interpreted like texts.

Jackson's efforts earned widespread acclaim, including conferences held in his honor. In recognition of his contributions, the Association of American Geographers established the J. B. Jackson Prize, awarded to those who disseminate geographical ideas to a popular, nonprofessional audience.

JEFFERSON, THOMAS (1743–1826)

President of the United States from 1801 to 1808 and author of the Declaration of Independence, Thomas Jefferson was also a passionate intellectual, accomplished scholar, philosopher, scientist, agronomist, musician, polymath, man of letters, and geographer. In addition to his accomplishments as president, ambassador to France, and founder of the University of Virginia, Jefferson maintained an active interest in the geography of North America, particularly as it pertained to its exploration and potential settlement. Along with Jedediah Morse, he is sometimes called one of the founders of American geography.

Jefferson's interests were both intellectual and pragmatic. He was fascinated by many things geographical, including maps and the accurate measurement of Earth's surface, mountains and geomorphology, climate and weather, and agricultural land use. As president, he directed his corps of engineers to record the nature of plants, birds, snowfalls, and forest clearance. Jefferson's volume *Notes on the State of Virginia*, a study of the climatology of his native state and its relations to humans, published in 1787, was one of 6,000 books in his possession (including 300 on geography), all of which were donated to the newly formed Library of Congress in 1815.

Jefferson and Hugh Williamson wrote the Land Ordinance of 1784, which established a rectilinear survey format in part designed to allocate land to Revolutionary War veterans. Later, the Ordinance became the U.S. Public Lands Survey System, the mechanism for the imposition of the Township and Range method of land surveys widely used west of the Appalachian mountains. Enormously influential as a cadastral scheme used in demarcating private property as well as state and county boundaries, the Township and Range system exemplified the values of the European Enlightenment, the imposition of an orderly, systematic frame of meaning that rationalized the largely unknown wilderness to the west.

Jefferson met Alexander von Humboldt several times in 1804, exchanged maps with him, and corresponded with him (in French) over several years, resulting in the two becoming close friends. He negotiated the Louisiana Purchase in 1804, doubling the size of the United States, and sponsored the Lewis and Clark Expedition through the American West during 1804 to 1806.

Finally, as one who viewed education as essential to a democracy, Jefferson was also an avid supporter of geography in schools. When he was governor of Virginia, he proposed that the discipline be taught in all school academies. In 1817, long retired, he drafted a curriculum for public education that included geography in all primary and secondary schools. Jefferson also insisted that it be included in the courses taught at the University of Virginia, which he founded.

JOHNSTON, R. J. (1941–)

One of the most prolific human geographers of the past half-century, Ronald J. Johnston is best known for his research in the areas of political and electoral geography, the history of human geography, and urban social geography. He is highly regarded for his work in political geography; he was one of the geographers who led the resurgence and revitalization of the field starting in the 1970s. Within political geography, Johnston's work has focused primarily on electoral geography, with an emphasis on the British electoral system. Along with Peter Taylor, he authored the main foundational text in electoral geography, *Geography of Elections*, in 1979.

Johnston was born in England. He received his BA and MA from the University of Manchester and his PhD from Monash University in 1967. He is currently a professor in the School of Geographical Sciences at the University of Bristol. He has previously served as vice chancellor of the University of Essex, professor and chair of the department of geography at the University of Sheffield, and a faculty member in the department of geography at the University of Canterbury in New Zealand.

Johnston is a leading writer on the history of human geography since World War II. He is the author of the leading book on the topic, *Geography and Geographers: Anglo-American Human Geography Since 1945*. In terms of his work in urban social geography, Johnston is best known for his work on (a) segregation and residential

differentiation and (b) the role of place in geography and the social sciences (the latter being the subject of his acclaimed 1991 book, *A Question of Place*).

Over all, Johnston is the author or coauthor of 50 books, editor or coeditor of an additional 40 books, and author or coauthor of over 800 journal articles and book chapters. He has received numerous honors for his research, including awards from the Royal Geographical Society and the Association of American Geographers, as well as being awarded honorary doctoral degrees from the University of Essex, Monash University, and the University of Sheffield.

JUSTICE, GEOGRAPHY OF

Scholars in many different fields have dealt with the topic of justice. For some disciplines, such as philosophy, political theory, and law, justice is one of the central concerns. Some of the most widely read contemporary authors from those

fields are theorists of justice, such as Iris Young, John Rawls, Charles Taylor, and Will Kymlicka. Goals in work on justice in the social sciences and humanities have included the following: defining justice, attaining justice, and denouncing and correcting injustices. More than a field in and of itself, justice has been an ethic applied in many disciplines, approaches, and methodologies.

How to think about justice has been, in and of itself, a focus of much work. Whether justice should be conceived individually or collectively, whether it is something to be decided through institutional legal means or beyond, and who decides when a situation is just or unjust are some of the questions addressed by those who engage the theme of justice. Quite often, perceptions of new injustices or new formulations of what would constitute a more just society arise not within the so-called ivory tower of academia but outside it, although the academic world is increasingly engaged with its surrounding social context. In fact, the social sciences have often become more attuned to the diverse questions surrounding justice due to the actions of social groups in the public sphere (e.g., the civil rights movement pushed many researchers to deeper engagement on the question of racial justice).

The geography of justice focuses on the spatialities of the question of justice—how phenomena such as international development, peace and war, racism, sexism, class inequality, environmental destruction, and more have specific spatialities to them. Particular spaces or spatial configurations can produce or maintain a situation of injustice. Additionally, a spatial approach can help correct an unjust situation. Thus, identifying these spatialities is one of the primary focuses of geographers working on questions of justice.

There is no clear starting point at which geographers began to work on this theme, and justice has been a concern of different geographers in many different specialties. Nonetheless, much of the recent work that focuses on questions of space and justice inherits from those subfields of geography that developed as a response to the different sociopolitical upheavals of the 1960s and 1970s, in particular (a) geographies of development, (b) feminist geographies, (c) geographies of race, (d) radical geography, and (e) Marxist geography. For many of these subfields, the highlighting and

analysis of an injustice and its spatialities is the central theme.

Through this work, geographers have been able to contribute new thinking to how questions of justice are approached. For example, even given formal legal equality and the legal end of segregation, geographic work has demonstrated how race continues to be a significant issue in countries such as the United States, through demonstrating inequalities in housing markets that create pools of poverty and electoral gerrymandering that hinders voters from choosing elected representatives responsive to their needs. Even what appears as the “straightforward” work of mapping socioeconomic data from the census or other sources has helped show how poverty and social exclusion do not work in the same ways across the board but are spatially concentrated in certain regions or types of spaces. Geographic work by feminists has demonstrated how spaces of social reproduction and care work (domestic work, child rearing, etc.) have been rendered invisible socially as well as legally and how these have historically been highly feminized spaces. Urban geography has demonstrated how the architecture and urban planning of a city, in and of itself, contributes to the inequalities between groups therein. Work in these fields concerning the geographies of justice focuses on many different scales, from the body to the neighborhood, to the nation and the globe, to producing or redefining scales as such.

Geographies of justice do not only refer to how injustice plays out in space or is created through the production of certain spaces, nor do they focus only on potential policy shifts that could address a particular injustice. Rather they also include struggles for justice, or battles against injustice, that take place through space. These struggles include attention to the spatial strategies of resistance practices, social movements, and other such actors. Some of these spatial strategies are (a) battles over access to space (e.g., antisegregation sit-ins); (b) claiming free or autonomous spaces (e.g., youth squatters’ movements); and (c) the creation of temporary spaces and scales through mega protests (e.g., the countersummits of the global justice movements).

Despite the concentration on the theme of justice in the subfields mentioned above, it should be

noted that geographies of justice have spanned, for the most part, the full gamut of methods and theoretical tendencies that have formed part of modern Anglo-American geography. This topic includes both quantitative and qualitative methods, users and practitioners of GIScience, and a wide variety of theoretical frameworks in human geography (especially from critical theoretical schools), be they Marxist, feminist, postcolonial, postmodern, poststructuralist, various combinations of these, and more. Geographers' concerns with justice have used both more traditional positivist methods for their work as well as post-positivist methods and critiques. Geographic work with justice has thus also had to challenge some older notions of "academic objectivity," at times redefining or questioning neutral objectivity altogether, in order to maintain the ethical goal of pursuing social justice as a guide for research.

It should be noted that geographies of justice are being worked on not only by geographers in many of the subfields of geography but far beyond the disciplinary boundaries. Many other fields of the social sciences and humanities have begun to discuss similar issues and have used geographical concepts as key tools in addressing situations of injustice. This could be seen as the result of the "spatial turn" currently afoot in many academic fields. In addition to other disciplines though, much work on the geographies of justice has taken and is taking place outside the university spaces proper. Much of this can be seen in the growing field of countermapping, which includes participatory projects between academic geographers and community geographers, such as the geographical expeditions of William Bunge and many experiments in indigenous cartography. There is also the increased use of maps by artists to denounce certain situations or to create alternative spaces, such as antiwar maps, maps of access to public spaces, and more. Activist or militant cartography is yet another example of this trend, where social movement networks explicitly

engage in a cartographic project to further their struggles around a particular issue. This trend is the case for the growing number of activist maps dealing with the creation of a new Pan-European Union border and its negative effects for migrant rights.

From this vast diversity, at least one thing is clear. Geographers of all sorts (both within and outside departments) are using the gamut of geographical tools to address situations of injustice or to create social justice. Given the "spatial turn" in Anglo-American social sciences and humanities, as well as the explosion of spatial, and especially cartographic, tools to the general public, the use of geography in the pursuit of social justice seems to be only spreading. While geography is not a panacea, from the already existing examples, it proves to be a useful tool for creating spaces of justice.

K

KANT, IMMANUEL **(1724–1804)**

Best known as a philosopher primarily concerned with ethics and epistemology, Immanuel Kant was also an important figure in the history of geography, although this aspect of his career is often overlooked. Indeed, he lectured on geography and numerous other topics at the University of Königsberg for 40 years (from 1756 to 1797), a century before it became a university discipline.

Kant's Philosophy of Time and Space

Essentially, Kant tried to resolve the debate between British empiricists and Continental rationalists. He was deeply affected by the works of David Hume, which he read for 11 years, and he accepted that true knowledge began with the senses, a position held by the empiricists; however, he departed from Hume in arguing that the mind is predisposed to a rational organization of sense data. Thus, he maintained that humans never experience things in and of themselves (noumena) but only perceive sense impressions of them (phenomena); we can know nothing about noumena and lots about phenomena. Since we only know a small part of the world at large, the domain of noumena must always greatly exceed that of phenomena.

In a sense, Kant was one of the first philosophers to problematize the matter of perception.

He held the view that the world has no preexisting given order (thus breaking from Aristotle) but is instead constructed by the rational mind—a position that aligned him with rationalists such as Descartes. Thus, instead of the mind revolving around the world, Kant viewed the world as revolving around the mind. Most important for geographers, he asserted that both time and space are categories created by the mind to make sense of nature: Time and space are not phenomena themselves but only ways to organize observable phenomena and impose order, logic, and meaning on the senses. In his most famous work *The Critique of Pure Reason*, published in 1781, Kant argued that reason and rationality are functions of a detached, disembodied observer, akin to Descartes's cogito. In this reading, nature is an external reality, mind is an internal reality, and knowledge is the means of overcoming this dichotomy.

Kant's epistemology differentiated between metaphysics on the one hand and the theoretical and empirical sciences on the other. He defined metaphysics as the analysis of a priori knowledge, including ethics and theology. Although Kant was personally religious, his emphasis on rationality was an important step in the secularization of science. The theoretical (or what he called "exact") sciences included disciplines such as physics and chemistry, which deploy deductive logic to decipher the universal laws of nature independent of time and space. The empirical (or what he called

“rough”) sciences, in contrast, were concerned with finding patterns and order in the welter of observable phenomena embedded in time and space; whereas deductive sciences were concerned with similarities among observations, the empirical ones were focused on finding the differences among them. The empirical sciences were essentially those concerned with time and place—that is, history and geography, respectively, which Kant put on a par in terms of their significance (i.e., the geographic location is as important as the historical context). The widespread privileging of time over space occurred much later, during the rise of 19th-century neo-Kantian historicism. Essentially, Kant argued that history and geography were concerned with understanding unique events. He further asserted that all causality was inherently a function of phenomena being located close in time and proximate in space, a primitive sort of Tobler’s First Law, which asserts that everything is related to everything else but near things are more related than distant things.

Kant argued that time and space formed necessary conditions for the perception of reality and thus for imposing a conceptual order on the world but they could not, by themselves, measure anything else. In some respects, he essentially upheld a Euclidean and Cartesian view of absolute space. Yet Kant’s view was more complex than this notion: While he enshrined Euclidean geometry as the architecture of the mind—a structure, like time, that made experience possible—he also disavowed the Newtonian notion of absolute time and space because it did not allow room for how they are experienced by people, thus introducing the issue of human perception. He did not simply dismiss time and space as subjective illusions but maintained that time and space are “real” only inasmuch as the mind perceives them and makes order of them. Although space existed *a priori*—that is, prior to experience—it could not be understood independent of experience. This argument shifted the focus from the world as it is in itself (noumena) to the world as known by human beings (phenomena) and elevated the question of sensory experience and its relations to reality to an epistemologically critical level. Experience is the continual synthesis of perception, and time and space are thus products of the mind—the tools it uses to render reality legible and meaningful. Such a view can

be seen as an intermediary between the view of space as absolute (i.e., as a container) and relative space (i.e., as relations among objects). This argument not only helped secularize time and space but also lodged their genesis within the individual mind, thus constituting a critical moment in the ascendancy of bourgeois individualism.

Kant’s Contributions to Geography

Kant made a number of important contributions to the emerging Enlightenment era’s understanding of space. He held that geography consisted of the study of people and their relations to the material world—that is, the exterior world outside the self, not the interior world of the mind, which he saw as anthropology. He differentiated between “mathematical geography” (essentially geodesy and map projections), physical geography, political geography, moral geography (spatial differences in customs), commercial geography (essentially trade), and theological geography (i.e., religious views of landscapes).

Most of Kant’s lectures were primarily concerned with physical geography: He wrote papers on earthquakes, rivers, the atmosphere, volcanoes, and the oceans, and 35 sets of student notes were collected in a textbook called *Physical Geography* (although there is some debate as to their accuracy and they have yet to appear in English). Geography included the study of races as part of physical geography, and Kant’s geographical works often exhibited an embarrassing lack of accuracy as well as overt racism and environmental determinism.

Kant also addressed the possibility of an international confederation of nations in his essay “Towards Perpetual Peace” (1795/1991), in which he argued that war could be made obsolete through a rigorous system of global laws and international commerce. Thus, he argued that “the peoples of the earth have entered in varying degrees into a universal community, and it is developed to the point where a violation of laws in one part of the world is felt everywhere” (p. 107). In this respect, he was a foundational thinker of the doctrine of cosmopolitanism and marked a turning point where morality could be formulated beyond the state form, and he thus

signifies the single most important source for normative theories of transnational relations. However, Kant wrote on the eve of the hegemony of the nation-state, and his views anticipated the rise of international organizations in the 20th century, such as the United Nations.

Finally, Kant publicly asserted that geography was critical to a general education; his enormous stature helped make the discipline respectable. His works were particularly influential with later neo-Kantian geographers such as Alfred Hettner and Richard Hartshorne.

KARST TOPOGRAPHY

Karst (in German) topography is the name for the many landforms that developed on the surface and within soluble rocks as caves and other forms characteristic of a part of the Kras region of Slovenia, where the landforms developed on and in some 400 square kilometers of limestone (calcium carbonate) and were first studied many years ago. All rocks can be slightly soluble in water, with the result that various karstic landforms can also develop more slowly in the somewhat less soluble magnesium carbonate of dolomite or dolostone, as well as quite quickly in evaporate rocks such as rock salt or gypsum. In fact, some solubility can even occur slowly in silicate rocks such as sandstone, especially where it is cemented with carbonate minerals, or quartzite, basalt, and granite under favorable conditions and over long time periods. The processes of karstification of a region involve dissolution of the bedrock as various minerals are dissolved in the water. Limestone bedrock, the most common host rock of karst topography, is composed of the mineral calcite, which is subjected to the carbonation reaction in the presence of water with a small amount of dissolved carbon dioxide that makes a weak carbonic acid. As this slightly acidic water comes in contact with the limestone bedrock, it has the capability of dissolving and carrying away molecules in solution to make the karst topography. For karst topography to develop best, however, the carbonate must be thick, mechanically strong, and well jointed to allow concentrated percolation locations for the infiltrating water to carry away the solute loads. Chalk rock, for example, is quite a pure form of limestone, but it does not form caves or karst well because it is neither mechanically strong nor well jointed; instead it is soft and crumbly, therefore cave systems cannot become established.

Karst topography is terrain formed in soluble rocks that bears distinctive characteristic of drainage and relief unlike most other landscapes. Instead, it tends to have a rough surface with many enclosed depressions; the soil above the bedrock tends to be thin and patchy, with exposed bare rock that is etched into a great variety of irregular shapes, and much of its drainage is

subterranean where it flows through caves and grottos. *True karst* occurs where solutional processes dominate; in some parts of the world where karst processes create almost all the landforms of the region, it may be appropriate to refer to it as “holokarst.” On the other hand, *fluviokarst* occurs where the processes of rivers and solution are approximately equal in their activities. Large parts of the Midwestern United States, for example, are dissected by rivers running over and through carbonate rocks so that the intervening interfluvies can have karst topography developed on and in them. *Glaciokarst* is formed in some areas of higher altitude and latitude where soluble carbonates occur beneath partial covers of ice so that as the glaciers wax and wane, their meltwaters can assist in the excavation of the subterranean topography. *Psuedokarst* landforms are

developed by the very wide variety of nonsolutional processes that mimic some of those of true karst. Thus, granular disintegration of silicate rocks, hydraulic plucking and wave erosion of sea caves, lava flows that have internal lava tubes or caves where the molten rock flowed out, and mass movements that open out chambers underground and produce hummocky topography on the surface can all produce psuedokarstic landforms. *Thermokarst* is rather a misnomer in that it is not a karst at all, has no solutional component whatsoever, and instead is entirely due to the melting of permafrost and ground ice, although its surficial appearance of enclosed depressions may superficially resemble a true karst.

Bare karst occurs where the soluble bedrock is exposed directly to the atmosphere, and *covered karst* has the bedrock beneath mantles of regolith

sediments and soil. *Free karst* has drainages that go unimpeded directly to the ocean, whereas *impounded karst* is surrounded by other less permeable lithologies so that the drainages have to exit in the karst area with a different sort of hydrological system.

From the standpoint of hydrology and depth in the Earth, karst is divided into the surface and near-surface zones of the *epikarst* and the deeper subsurface zones of the *endokarst*. Epikarst is the karstic region in the vadose zone above the water table where there are air-filled openings as well as some water in the openings. Epikarst occurs from the surface and soil of the cutaneous zone, as well as the regolith and enlarged fissures of the subcutaneous zone. In these zones, close to the surface, precipitation is the chief input and evapotranspiration an output. At the base of the epikarst, there is a continuum of percolation involving seepage, trickles, and flows, up to full cave streams. Endokarst, below the epikarst, has the vadose zone of unsaturated percolation and water flow at its very top down into the phreatic zone of saturated water flow below the water table wherein water-filled fissures and pores occur, as well as fully water-filled caves. Outflow springs from the endokarst and epikarst areas occur at many different levels on the surface around higher topography with caves inside it.

Linear caverns in karst areas are *vadose caves*, which are above the water table; *shallow phreatic*, *epiphreatic*, or *water table caves*, which occur right at the water table; or *phreatic caves*, which are entirely below the water table. These basic cave types also have variants in which irregular cave passage loops occur, either entirely up and down beneath the water table as deep phreatic with loops or phreatic with loops that project a little way above the water table so that they become air filled for short distances. In addition, there are mixed loop and epiphreatic caves that have substantial parts both above and below the water table.

Because karst landforms are unusual in appearance and are distributed all over the world, so that a huge and confusing lexicon of descriptive and attempted genetic terms has arisen in many languages to describe them. Multilingual synonyms abound. The following is a brief exposition of some of the better-understood forms,

although it should be realized that fine divisions between some landforms may reflect continua of form and process such that absolute differentiation between types may be somewhat ambiguous at times.

Karst landforms are many and highly varied. Perhaps the best way to consider these landforms is by their size scale, as well as whether or not they are on the surface or underground as subterranean landforms. In addition, karst landforms can be classified based on whether they are positive landforms that resulted from rock having been removed from around them or from material that was deposited to make them or negative landforms wherein material has been removed to leave an opening of some kind.

On the surface where the larger landforms occur, which are most commonly observed as being of karst origin, perhaps the most common are the sinkholes, or dolines. Five main kinds of dolines occur, the solution, the suffusion, the collapse, the subsidence and the stream-sink types. *Solution dolines* occur where the dissolving of the bedrock is concentrated at some intersection of joints or some other favorable circumstance where solution was concentrated. Insoluble residues can eventually clog the drainage so that a *pond doline* results. *Suffosion dolines* are those formed by the processes of a through wash where sediments are carried away both in solution as well as by suspension so that a depression results that is generally fairly well choked with debris. *Collapse dolines*, such as the famous vertically sided *cenotes* in the Yucatan in Mexico, are those where the roof of a cave collapses. Over time, with no further collapse, the vertical walls will degrade and become less steep so that bowl- or cone-shaped dolines can result. *Subsidence dolines* result where a quite soluble rock such as rock salt dissolves and allows the settling or subsidence of overlying sediment or rock without any obvious fracturing or breaking of it. *Stream-sink dolines* or *ponors* form where streams flow down into swallow holes in carbonate rocks and then pass underground.

Uvalas are compound sinkholes that have developed a larger depression complex. As the size increases, a *polje* (plural *polja*)—a large, flat-floored, and closed depression—is formed. Both uvalas and *polja* commonly have permanent or

ephemeral streams in them that disappear into dolines. Polja can be subdivided into a number of different types depending on their relationships to the surrounding geology and hydrological systems. For example, *border polja* have rivers coming into them from outside nonkarst areas that are controlled by the external water tables so that lateral planation and alluvial deposition occur in the polje. *Structural polja* have downfaulted zones of permeable soluble rocks juxtaposed against insoluble rocks. *Baselevel polja* have regional water tables that intersect the ground surface inside them so that they flood periodically.

An *eggbox topography* forms where the limestone is thick and the water table deep so that deep solutional sinkholes form close together. A *cone karst* develops where the sinkholes coalesce together, and the region is dominated by projecting residual relief rather than by closed depressions. The result is a polygonal pattern of ridges around separate dolines. *Cockpit karst* has lower ridges and residual *pepino* hills, whereas tower karst has huge residual hill towers or *mogotes* (haystack hills) that can be steep enough or with vertical and overhanging sides to form a *pinnacle karst*.

Fluvial aspects of karst topography beyond those mentioned above include blind and half-blind valleys, steepheads or pocket valleys, dry valleys, meander caves, natural bridges, and tufa and travertine deposits. *Half-blind valleys* are those where a stream develops a swallow hole and downcuts a small amount upstream from the sink to leave the downstream portion only occasionally still hosting flood waters. A *blind valley*, on the other hand, is one that is closed off at its lower end by a cliff or steep slope facing upstream, below which the stream disappears into the sinkhole of a cave opening. Dry valleys have no surface stream in them, although they once did until the original stream that formed them found and exploited some subterranean exit point to abandon them. *Steepheads* and *pocket valleys* are those where a river emerges from a cave at the head of a valley. *Meander caves* are those where the outer bend of a meander in a karst area undercuts a limestone valley side so that a large overhanging cliff and cave system develops beneath. Karst *natural bridges* form where cave roofs collapse upstream and downstream from the bridge,

where subterranean stream piracy has diverted water beneath them, or where rivers dissolve their way through narrow bands of limestone that cross their paths. Tufa and travertine deposits can be produced by rivers in karst areas because water bodies there are commonly supersaturated with dissolved carbonate. Any disturbance to the water in rapids, waterfalls, or agitated flow through aqueous vegetation or the like on the surface may allow a small amount of carbon dioxide to escape from the water or a bit of water to evaporate, which then can cause some calcium carbonate to precipitate from the water. This carbonate buildup occurs in two main forms: (1) the porous and low-density *tufa*, which commonly has many root and stem casts inside it where the carbonate came out of the solution and precipitated around water plants, and (2) *travertine*, which is compact, of higher density, crystalline, and commonly banded and layered where variations in the water have changed the crystallization character or composition somewhat over time. Together, tufa and travertine can accumulate in masses large enough to constitute dams, mounds, sheets masses, and many other forms.

An additional discussion of karst includes a discussion moving down in scale to the smaller forms. A general term for many types of these smaller forms includes *karren*, which are a highly diverse group of small-scale features and sculpted forms of the bedrock that are exposed on the surface of the ground or that appear inside caves. Bare karst forms can be produced by wetting caused by rain or snowmelt hitting and flowing over the surface or dripping onto and seeping into it to carry away dissolved load. The small landforms that these processes produce are quite common in soluble carbonates but may also be produced on silicate rocks where certain mafic minerals (e.g., amphibole, pyroxene, and some micas) can weather more quickly to produce some solution and granular disintegration from differential decomposition that allows development of similar appearing landforms. The smaller karst landforms produced by solution can be subdivided into (a) bare karst forms produced by surface wetting, (b) bare karst forms produced by concentrated surface runoff, (c) partly covered karst forms, (d) covered karst forms, and (e) polygenetic forms or assemblages of karren. In many

cases, it may be quite difficult to determine whether or not a form was produced while it was covered with moist regolith or saprolite above it and later exhumed or whether it was generated entirely while partially or fully exposed to the atmosphere, or some odd combinations of both these possibilities.

The bare karst forms produced by wetting are scale dependent and include the following, in more or less increasing size: (a) *micropits* and *etched surfaces* are produced by precipitation falling on gently sloping or flat bare rocks to form small pits and rills less than 1 millimeter deep and not larger than a few centimeters; (b) *solution ripples* and *fluted scallops* are shallow, ripple-like flutes that form on steep to vertical surfaces perpendicular to the direction of the water flow over them; (c) *solution flutes* or *rillenkarren* are longitudinal hollows that start at the top of a rock crest and run down the steep rock surface with either rounded (silicate) or sharp (carbonate) ribs between them; (d) *solution bevels* are smooth and flatish tiny risers and treads in stair-step forms; (e) *solution runnels* or *rinnenkarren* are the larger solution hollows that result from larger volumes of overland flow; (f) *decantation runnels* are related to solution runnels that result from the dripping of acidified water from point sources upslope that are either in direct contact with the surface or not, or still exist as a present-day source or not, so that the resulting runnels in the rock can meander and/or reduce in size downslope; and (g) decantation flutings are similar to decantation runnels but have water sources at their heads that are diffuse sheet flows from upslope.

On the other hand, the bare karst forms that are instead produced by concentrated surface runoff also include, in order of more or less increasing size, the following: (a) *microfissures* follow thin small joints up to several centimeters in length but less than 1 centimeter in depth; (b) *splitkarren* or *solution fissures* occur along joints, veins, or stylolite solution features formed between bedding plains that are several centimeters to several meters long and some centimeters deep; (c) *solution slots* or *grikes* and *kluftkarren* are fairly large solution features developed along structural discontinuities such as large and connected joints or faults and can ultimately result in quite accessible and spacious *bogas* openings in the karst, as well

as karst *corridors* and karst *streets*; (d) *clints* are the tabular blocks left between grikes (solution slots); and (e) *solution spikes* or *spitzkarren* are the steep projections between grikes.

The partly covered karst forms that occur include (a) *solution pits*, which are round-bottomed or tapered forms, and (b) *solution pans*, which are dish- or basinal-shaped depressions formed on flat rock surfaces resulting from bedding planes or joints, which may have sides that overhang or carry solution flutes above bottoms covered with organic remains, clay, silt, sand, and pebbles. These two forms of solution pits and pans together are the most common of all karren forms. In addition, other partly covered karst forms are (a) *undercut solution runnels* (*hohlkarren*), which are similar to runnels but become larger with depth as a result of the damper conditions at their bases due to accumulations of soil and/or humus, and (b) *solution notches* (*korrosionkehlen*), which are inwardly curved lateral depressions or recesses produced by chemical etching from damp soil directly abutting the bedrock.

The fully covered karst forms have acidic sediment and soil above them in which the moisture is retained, and this helps them develop as (a) *rounded solution runnels* or *rundkarren*, which are smoothed out by their contact with the cover materials; (b) *cutters*, which are soil-covered solution slots (grikes) that are wider at the top and taper at depth; and (c) *solution pipes, shafts, or wells*, which are conical or cylindrical holes that can develop along joints or in an isolated fashion in unjointed carbonates such as chalk.

Polygenetic karst forms are commonly assemblages of different karren types. They include the following: (a) *karren fields*, exposed tracts of karren that may be as large as several square kilometers; (b) limestone pavements, where numerous soil-covered or bare solution slots (grikes) separate exposed rock surfaces (clints) that can be covered with karren forms, which either developed in the subterranean environment or subaerially, or both but in sequence; (c) *pinnacle karsts* and *stone forests*, a spectacular karst landscape with thin and pointed rock remnants that can be 45 m (meters) tall and 20 m wide at the base, although some tropical forms are known to stand as high as 120 m, with near-vertical sides and sharp, saw-tooth tops; (d) *ruiniform karsts*, a type of karst

wherein the upstanding tabular clints in between the well-developed, wide-solution slots are so well developed that after extensive soil erosion only a few upstanding blocks protrude upward like ancient ruined buildings scattered out in a former cityscape; (e) *corridor karsts*, which develop where large solution slots grow bigger and form aligned or crisscrossing steep-sided valleys that may develop into *labyrinth karsts* or *giant grikelands*; and (f) *coastal karrens*, which develop in the common carbonates along shorelines so that *solution notches* or *nips* develop in the rock exposed above shoe platforms, as well as a dense and pervasive variety of pits, pans, and spikes that may have been partly aided by boring and grazing organisms that can assist in producing *biokarsts* and partly by wave action, wetting and drying, salt weathering, or some plant activity to produce *phytokarst*.

KATES, ROBERT (1929–)

Robert (Bob) W. Kates is one of the world's leading geographers of the past half-century. He has said that from the beginning, his grand query was "What is and ought to be the human use of the Earth?" Since 1958, Kates has focused on three main issues: (1) living with hazard, (2) ending hunger, and (3) sustaining life on Earth. He has played a major role in the development of sustainability as a transdiscipline.

Kates was born in New York City in 1929. In his late 20s, he was supporting a young family by working in industry in the Chicago area, having left college without a degree to get married, when he signed up for a night course at a local university that was taught by one of Gilbert White's graduate students at the University of

Chicago. A year later, he was admitted to graduate school in geography at Chicago. Kates began his graduate study in 1958 in an interdisciplinary effort to understand floodplain management. He became geography's most vivid example of the value of second chances. Not since Gilbert White, who became his mentor, has there been a geographer who has so notably shaped research on nature-society relationships. Most of his career was spent as a geography professor at Clark University in Worcester, Massachusetts.

In considering how societies and individuals assess and respond to environmental and other hazards, Kates has led the way in introducing risk assessment perspectives and paying attention to how local rationalities may differ from those of external analysts, both in the United States and in developing countries. His insights about ending hunger have been developed from his experience with hazard modeling, looking into what factors lead to inadequate food supplies and the ways in which that knowledge can be combined with action to reduce hunger.

Since he published a classic paper on sustaining life on Earth in *Scientific American* in 1994, Kates has been a driving force behind the emergence of sustainability science as a new transdiscipline. He coled the preparation of a U.S. National Research Council report (1999) that broke new ground in identifying the challenges both to science and to converting science into action, as did a 2001 paper in *Science* that established a new quasi discipline of sustainability science for research and practice.

Kates's work has earned him major recognition, unmatched by any other geographer in his generation. In 1975, he was elected to the National Academy of Sciences; in 1981, he was awarded a MacArthur Prize Fellowship; and in 1991, he was awarded the President's National Medal of Science in a ceremony at the White House in Washington, D.C. Even so, Kates has, in many cases, taken a path different from that of conventional geographical scholarship. From the beginning, he showed an interest in questions that mattered as much to society as to science. Perhaps influenced by his early immersion in group research, he has actively sought challenges that are too large for any one individual.

Since receiving his PhD in 1962, he has thrown himself into not only contributing to science but

also making his local area better, as he now does in Maine. He shows every day how much he cares about a host of colleagues, collaborators, and former students; and he has no priority higher than his family—his wife, three children, and six grandchildren. It is no accident that he formulated what might be called “the Kates discount rate”—the discount rate applied by grandparents to future benefits for their grandchildren, for whom those future benefits have a higher value than the current costs.

KEYSTONE SPECIES

Keystone species are plants or animals that have important effects on a particular ecosystem’s biodiversity and function, despite having a relatively low abundance. The term *keystone* originated in the field of architecture to describe a centrally located wedge-shaped stone that supports an entire arch. Robert Paine, an American ecologist, first introduced the keystone species concept to ecology in 1966. The meaning of the term in ecology is analogous to its meaning in architecture; similar to the support function of a keystone within an arch, a keystone species is considered a main supporting component of an ecosystem, without which the system would fail. The loss of a keystone species could result in the

loss of several dependent species and critical ecosystem functions.

Paine’s original usage of the term *keystone species* referred specifically to the high trophic position and unique function of a particular predatory starfish species found in a rocky marine intertidal zone. He found that the starfish’s activities clearly modified the species composition and physical appearance of the ecosystem, more than the activities of other predators. The actions of the starfish clearly served to regulate biodiversity in the ecosystem.

In the years since the introduction of the concept, the definition of the term has broadened to include any species with uniquely strong, positive effects on biodiversity regardless of its trophic level; however, the term still has different meanings to different people. A general, current definition of a keystone species encompasses plants, primary consumers, or even species that make important physical modifications to an ecosystem through its daily activities. Thresholds are particularly relevant to keystone species because when the density of a keystone falls below a given level, the biodiversity of the ecosystem is likely to decrease, affecting the balance and stability of the entire ecosystem.

Keystone species differ from *foundation species*. While foundation species serve essential ecosystem functions and affect biodiversity, their impact is primarily the result of their abundance. Keystone species, however, are generally not recognized as being abundant in the ecosystems in which they have a critical role sustaining a biologically diverse environment. Regardless of its classification, the loss of either foundation or keystone species can be detrimental to ecosystem functionality.

Importance of Keystone Species to Biogeographic Distributions

Understanding geographic distributions of plants and animals requires knowledge of both the physical environmental variables (such as light, temperature, and moisture) and the interactions among plant and animal species (such as predation and competition) that limit species’ distributions. In biogeography, the strong biological effects of keystone species provide a compelling example of biotic interactions that can influence

species' geographic ranges. Because keystone species affect competition regimes, ecosystem stability, biodiversity, species density, predation, and resource availability, their presence also indirectly influences where some species are found and where they are absent. Decreases in abundance or removal of the keystone species may result in changes in the distribution not only of the keystone species but of other plants and animals as well. Such distribution changes could affect the flow of energy and nutrients throughout the ecosystem. To geographers and others who study the effects of environmental change and human-environment interactions on biogeographic distributions, the keystone species concept should be considered.

Classification and Examples of Keystone Species

The keystone species concept has been used increasingly by ecologists, biogeographers, and conservation biologists to describe the diversity of important interactions of relatively rare species whose actions influence a diversity of ecosystem functions. One outcome of this broadened recognition is the development of specialized classifications and terminology that describe the multifaceted functions of keystone species. L. Scott Mills and colleagues comprehensively reviewed several categories of keystone species found in the ecological literature. The most common classifications include keystone predators, keystone plants, and keystone modifiers.

Keystone Predators

A keystone predator is a predator that is found at high levels in the food web. A predator may be a keystone species when it controls the densities of certain competitive dominants or key prey species. In the absence of a keystone predator, other competitors may drive out species or decimate populations, resulting in a decrease in overall biodiversity.

Paine's work on marine life in intertidal zones provides the classic case of a keystone predator. He discovered the important interactions of the predatory starfish *Pisaster* in a rocky intertidal zone through experimental removal of the species.

He found that the removal of *Pisaster* led to population explosion of certain mussels and sea urchins, resulting in ecosystem diversity lower than conditions prior to the experiment. Paine's classic work showed that without keystone predators in this particular marine ecosystem, the overall balance of the ecosystem was upset and unpredictable results followed. Though Paine conducted his work in a marine environment, his findings had important implications for many different ecosystems.

Several scholars (e.g., J. Estes and others) consider the sea otter (*Enhydra lutris*) to be a keystone predator because of its important role in limiting the density of sea urchins, a primary consumer of kelp and micro algae in some marine environments. In the absence of sea otters, the sea urchin population explodes, and the kelp population decreases, resulting in the loss of microorganisms that rely on the kelp for habitat and survival. Because of their important role in communities, changes in the population size of a keystone species is likely to have broad impacts on the way the ecosystem functions.

Keystone Plants

Keystone plants are those plants whose removal could result in the elimination of a series of animals and other plants that are collectively dependent on the keystone plant. Often, such dependents include pollinators and seed dispersers. Whitebark pine (*Pinus albicaulis*) is considered a foundation and keystone species of both the upper subalpine forest communities and the alpine treeline ecotone (ATE) of the North American West. Whitebark pine facilitates the development of tree islands in the ATE and thus serves an important role in the distribution of trees at the treeline. Additionally, as recorded by the wildlife biologist Katherine Kendall, its hard, nutritious seeds serve as an important food source for animals such as grizzly bears and squirrels. Whitebark pine also shares a mutualistic relationship with Clark's nutcracker (*Nucifraga columbiana*)—the sole disperser of its seeds, as investigated by the American ecologist Diana Tomback. The removal or loss of whitebark pine from alpine and subalpine ecosystems is likely to substantially affect these species, plus leading to cascading effects on other plant and animal species in downslope ecosystems.

The largest land mammal in North America, the bison's grazing patterns, movements, and behavior influenced the composition of grassland ecosystems 200 years ago. But in the 1800s, human settlement in the region led to the large-scale slaughter of bison and conversion of much of the grass prairie to agriculture. By 1900, this keystone species was nearly extinct. Today approximately 450,000 bison exist due to reintroduction efforts, but more than 95% are in managed private production herds, and the bison's ecological functions have not been restored.

Source: Morguefile.

Keystone Modifiers

Keystone species do not always affect other species through competitive or predatory activities. Keystone modifiers or *ecosystem engineers*, a term designated by Clive Jones, may indirectly affect the species of a particular ecosystem through habitat modification. Modifiers, by changing the physical state of an ecosystem, improve the resources available to certain species, increasing their survival rates. The North American beaver (*Castor canadensis*) may be considered a keystone modifier because of the effects of its damming on hydrology and the resultant

energy and nutrient flow through the ecosystem that results in increased habitat heterogeneity.

Allen K. Knapp and other ecologists have identified the North American bison (*Bison bison*) as a keystone species of the tallgrass prairie. Their grazing reduces the abundance of certain grasses that are competitive dominants, along with woody vegetation from the prairies. Without the removal of the woody grass species, the tallgrass prairie would eventually become a forested environment. Through their preferential grazing and wallowing activities, bison increase habitat heterogeneity and species diversity. Year-round grazing from bison and ungulates, along with natural fire regimes, are

thought to be key factors in the conservation of the remaining tallgrass prairie of North America.

Debates Surrounding the Keystone Species Concept and Ecosystem Conservation

The keystone species concept is one currently surrounded by debate. Keystone species are often at the forefront of discussions on the prioritization of ecosystem and habitat conservation. Within the realm of conservation, an inherent controversy associated with the keystone species is the implication that some species are more important to ecosystems than others. In light of the limited resources available for conservation efforts, proponents of this viewpoint argue that keystone species should be given priority in conservation efforts.

Many scholars, however, question whether the qualities of a single species can be so essential to an ecosystem as to warrant special status. Single-species approaches to conservation, such as preferential targeting of keystone species, may underappreciate the complexity of ecosystem function. Therefore, conservation approaches that emphasize one species may not be successful for long-term biological conservation. Some ecologists (e.g., L. Scott Mills and his colleagues) even call for the abandonment of the keystone species concept altogether because of its vagueness.

John Bruno, John Stachowicz, and Mark Bertness highlighted two primary problems associated with placing keystone species at the forefront of conservation efforts. First, is the difficulty associated with positive identification of keystone species and the strength of their interactions, which must be tested through experimental removal of species. Associated with this difficulty is that the strength of keystone species interactions with other plants and animals may vary from one environment to the next. Second, the ramifications of focusing conservation efforts on single species, possibly at the expense of other species (especially foundation species) that may also be important for ecosystem function and biodiversity, is problematic. Such narrowly focused conservation efforts could result in ecosystem collapse or instability, even with its keystone species population protected. Adaptation of a systems-based perspective to the problem of conservation requires

the recognition that ecosystems are inherently complex. Many ecologists argue that understanding interactions among species (and physical environment) is critical for proper ecosystem functioning and biodiversity protection and that consideration of the abundance of a single species achieves only partial resolutions to problems associated with ecosystem management, at best.

KNOWLEDGE, GEOGRAPHY OF

The geography of knowledge deals with spatial disparities in the generation, diffusion, and application of various categories of knowledge and skills. Spatial disparities in literacy, educational attainment, professional skills, creativity, and technology can be traced back to early human history. Some of their primary causes are spatial concentrations of power and knowledge created by the spatial division of labor, the hierarchical structure and complexity of organizations, the asymmetry and spatial range of power relations, and the ways in which social systems and networks are coordinated and governed in space. Communication technologies—from the creation of the first scripts to the invention of paper and from the construction of the first printing machine to the introduction of digital information systems—changed spatial disparities pertaining to the production, dissemination, and uses of knowledge but never abolished the disparities between the centers and peripheries of national or global urban systems with regard to the distribution of workplaces for highly and marginally skilled persons.

Knowledge can be defined as the capacity for social action; it influences perceptions and evaluations of information and the decision making and actions of persons. Knowledge and power build multifaceted coalitions that reproduce social and spatial inequalities. A head start in knowledge, expertise, and technology is an important prerequisite for competitiveness. All fields of human geography can be enriched by exploring the consequences of spatial differences in knowledge, expertise, professional skills, technology, or educational achievement and how these disparities can be explained. In addition, most political, economic, and social changes (e.g., colonialism, nation building, globalization, neoliberalization, privatization) have impacts on the educational system. This eminent role of knowledge and education in modern societies leads to numerous possible research topics within geography and entails necessary specialization and a large variety of theoretical concepts.

The Geography of Education

Political and scientific interest in spatial disparities of education harks back to the first decades of the 19th century. It was the time when social reformers in France and the United Kingdom believed that poverty, crime, and alcoholism were caused by ignorance and a lack of moral education and when relations between the degree of a nation's literacy and economic performance were discovered. In the 19th century, scholars in the social survey movement studied social and spatial disparities of illiteracy, the availability and quality of schools, the skills and salaries of teachers, and the educational attainment of children with regard to their family environment (e.g., the availability of books). Apart from occasional studies of the locations of schools and universities, of school transport, and of drop-out rates and truancy, human geography neglected spatial disparities in the provision and consumption of schooling until the mid 1960s. With the expansion and restructuring of school systems in the 1960s, spatial and social disparities of educational achievement and education as a means of social stratification, social exclusion, and regional development became a significant topic in geography. The first professor specializing in the geography of education was Robert Geipel. He started his research on spatial disparities of education in the early 1960s at the University of Frankfurt and inspired, in more than 30 years, many scholars to focus on this new field, especially when he was holding a chair at the University of Munich (1969–1994).

The newly emerging geography of education began first to study the location criteria, catchment areas and structural changes of the school and university system, the effects of school closures for community development in sparsely inhabited areas, the extracurricular activities of teachers as an interface between school and community, the spatial consequences of school reforms, and the cultural and economic effects of universities. Later topics included the movement of pupils through the school system; educational attainment and exam scores of students with respect to their place of residence, social origins, and ethnicity; spatial disparities of the educational achievement of the resident adult population and

their consequences; the spatial distribution of jobs for the highly and lowly educated labor force; the spatial mobility or circulation of talent; and the role of the educational system in the assimilation or seclusion of minorities. Transition rates of various age groups to the different types of secondary schools and colleges and universities; the median number of school years completed; the drop-out rates; the truancy rates; and other indicators of schooling are used to describe the spatial dimension of social structures and processes and to define inner-urban problem areas.

From the 1980s onward, work on the geography of education extended its research to spatial disparities of the sociodemographic structure of teachers and university scholars (e.g., age, skills, gender, ethnic origin, career, and spatial mobility); to relations between educational achievement, labor markets, and spatial mobility; and to spatial disparities of vertical social mobility between generations. At the same time, economic geographers attached increasing importance to the role of professional skills; the diffusion of technical innovations; the spatial distribution of patents, inventions, research input, and output; and the impact of clusters and networks on knowledge generation. From the 1990s onward, the geography of education turned increasingly to theoretical issues of knowledge generation and dissemination and to the nexus between knowledge and space.

The Geography of Science

The geography of science, which developed since the early 1980s mainly in the United Kingdom and the United States, is interested in all steps of the generation, dissemination, and application of scientific knowledge. Locally produced knowledge becomes widely disseminated knowledge only if it is shared with others, recognized by epistemic authorities of the relevant domain, and proved useful. A spatial context or setting in which scientific experiments and studies are carried out does not only influence the generation of knowledge, it also strongly affects the justification, legitimization, and dissemination of scientific results. Places of discovery can have an impact on scientific results. They present distinct opportunities of learning. They induce different

questions and discourses; foster different experiments, practices, and engagements; and have different scientific reputations. The acceptance and reputation of scientific results depend, to a large degree, on where they were generated, shown, and verified. The platform on which scientific results are first presented is often of more importance for their rapid diffusion than is the quality or originality of the findings. Science and the humanities are replete with examples illustrating the extremely long time it took for highly creative ideas, new research questions, and theoretical concepts to be perceived and accepted by the epistemological centers of the relevant disciplines.

David Livingstone described distinctive geographies of writing and reception, showing that the generation of knowledge requires a spatial context other than the showing of experiments and that the legitimization of scientific results, in turn, calls for other locations. A spatial diffusion of scientific knowledge does not guarantee that readers will interpret that knowledge as intended by the writer. Darwin's theory of evolution, for instance, was interpreted very differently depending on the country in question.

Geographies of Creativity

Since the late 1980s, it has become widely accepted that creative ideas emerge and develop in complex, dynamic interactions between the creator and his or her environments. Creative individuals are embedded in particular environments capable of either fostering or hindering their creativity. Cognitive processes are guided not only by personal capabilities or intrinsic motivation but also by interactions with the environment. A creative milieu is not produced solely by the copresence of particular constituents. Much more decisive are their interrelations and mutual modifications. A creative milieu or environment represents a certain possibility or potentiality that must be activated through human communication and interaction. The potential to communicate with other highly creative persons attracts other creative artists and scientists from elsewhere and thus enhances the attractiveness of a place. One cannot predict whether and how often this potential for integrating diverse viewpoints and knowledge bases is activated. This is one of the

reasons why many scholars hesitate to use the terms *creative industry* or *creative class*.

Knowledge and Power

The close dialectical relationship between knowledge and power, and the attraction of power centers for intellectuals and experts, may be regarded as the main reason for the long persistence and continuous reproduction of spatial disparities of socioeconomic structures. Work places of important decision makers, highly skilled specialists, and high-technology industries show a strong tendency toward spatial concentration, whereas low-skilled, routine activities in production and administration show a trend toward dispersion and decentralization. The main characteristic of peripheries is that they constantly lose the largest part of their highly educated people to the centers.

The importance of power to the production and dissemination of various types of knowledge (including orientation knowledge) can hardly be overestimated. Orientation knowledge provides values and a point of reference, declares what is good or evil, bestows identity, and forms the glue that keeps a social system together. Since early history, it has been in the interest of those in power to control or influence institutions of knowledge production and to manipulate and censor the diffusion of information. Since the 19th century, the school system is considered as one of the most important instruments in the socialization of the young. In most countries, the mission of the schools includes consolidating the nation-state by creating and transmitting national identities, ideologies, collective memories, and narratives and by assimilating ethnic minorities and immigrants. Throughout the 19th and 20th centuries, state authorities used the school system to control and discipline their ethnic minorities, to interfere in their cultural development, and to separate the elites from other strata of society.

Schools can also function as sites of ethnic resistance where historical experience and cultural practices of ethnic groups are cultivated. To preserve their culture, most ethnic minorities are eager to organize the education of their children in a certain way, at least in the first years of compulsory schooling. Schools represent a legal

means by which the minorities can protect their culture from intervention by the dominant political apparatus, which is normally the state. It makes a big difference whether an ethnic minority group may use its mother tongue as language of instruction and whether it has a chance to influence the way in which its history and culture are presented to its children. Therefore, the educational system and the language of instruction in schools emerged, during the 19th century, as a focal point of conflict between state building and the national emancipation process in multiethnic states. The language of instruction to be used in schools was of paramount instrumental value in both state nationalism and nation building. The unequal treatment, opportunities, and achievements of minorities in the school system are a fine seismograph for the degree of their vulnerability, their collective social status, and their discrimination and chances in the labor market.

As educational systems are highly context sensitive, generalizations about the impacts of educational policies or school reforms should be checked very carefully. The ideology and practice of decentralized governance (local control) may re(produce) racial segregation and interdistrict funding inequities in the United States but bring great benefits to disadvantaged ethnic groups in European countries. Depending on the context, high per capita income of a community may increase or decrease the transit rates to universities.

KNOWLEDGE SPILLOVERS

By knowledge spillovers, economic geographers usually refer to technical, scientific, or organizational knowledge that, once discovered, easily comes to the attention of other individuals due to its nonrival and (partially) nonexcludable nature. Nonrivalness implies that additional users bear no extra cost and do not prevent others from possessing and using the knowledge. Nonexcludability indicates that it is also impossible, or at least very difficult, to prevent others from gaining the knowledge, whether they have contributed to its production or not. The term *spillover* is intended to highlight the difficulty of controlling knowledge and preventing its unintentional dissemination in the economy. Now regarded as the central factor for economic growth, knowledge spillovers and their underlying circumstances have received increased scholarly attention.

A common assumption in the geography of innovation literature is that knowledge often takes the form of know-how or tacit knowledge, which is hard to convey by means other than repeated face-to-face interaction. When spillovers are thus locally bounded, firms tend to locate near their sources, such as universities, research and development (R&D) intensive firms, or skilled labor. Many empirical studies have therefore examined the impact of universities or labor mobility on regional growth, using various indicators. Patents and patent citations are now most commonly used in this respect, and in the case of scientific knowledge, various bibliometric methods are generating increased interest.

The most influential analytical framework to study the impacts of knowledge spillovers on urban growth was developed in 1992 by Glaeser, Kallal, Scheinkman, and Shleifer, who distinguished among three different perspectives:

1. MAR spillovers, referring to the original insights of the economists Alfred Marshall, Kenneth Arrow, and Paul Romer
2. Porter spillovers, named for the famed management scholar Michael Porter
3. Jacobs spillovers, named after the urban theorist Jane Jacobs

The first two approaches stress spillovers within a sector (intraindustrial spillovers) and the importance of geographical economic specialization, whereas Jacobs spillovers occur between sectors (interindustrial spillovers) and are therefore more abundant in a more diversified local economy. In addition, the MAR perspective favors local monopolies, whereas the other two see strong local competition as a better incubator of innovative behavior. Although much debate surrounds the issue, Jacobs's perspective has gathered most support from researchers.

While the empirical literature on geographically localized knowledge spillovers is extensive, many central questions remain unsettled. The main criticisms revolve around the issues of tacitness—spillovers as externalities—and the actual nature of spillover processes. For example, tacit knowledge was originally viewed as implying that individuals know more than they can tell. It was therefore not merely difficult but impossible to convey this through formal communication. In the more recent literature, a case is now sometimes made that the main difficulty in transmitting much expert knowledge has often more to do with other factors, such as cognitive rather than geographical distance.

Another problematic issue is that knowledge spillovers usually imply that the diffusion is unintended and that the innovator does not receive full compensation. Some scholars therefore use the term *knowledge externalities* interchangeably. In many cases, however, the characteristics of positive externalities are not satisfied, or this proves difficult to verify. Finally, the numerous

empirical studies based on knowledge spillover proxies do not document or even prove their existence, and other explanations or factors might be more significant.

While the importance of knowledge spillovers for the geography of innovation is not likely to falter, improved theories and detailed empirical studies are increasingly called for.

KÖPPEN, WLADIMIR (1846–1940)

Wladimir Peter Köppen was born on September 25, 1846, in St. Petersburg, Russia. Although best known for his climate classification system, he was originally trained as a botanist. His scientific work, which includes 526 published research articles and numerous books written between 1868 and 1940, is recognized in the fields of geography, meteorology, climatology, and botany. He died on June 22, 1940, in Graz, Austria.

Köppen lived in Russia until he was 20 years old. He had an early curiosity about the environment due to his mother's interest in botany and the family's travels. He started his studies at the University of St. Petersburg in 1864. He later

went to the University of Heidelberg for graduate studies. In 1869, Köppen transferred to the University of Leipzig, where he studied climate impacts on plant growth. He earned his doctoral degree in 1870.

Köppen worked for the Central Physical Observatory at St. Petersburg from 1872 to 1874, where he published 12 research articles. He moved on to the North German Sea Watch, a naval observatory in Hamburg, in 1875, where he developed a forecasting service for northwestern Germany and nearby waters, described the motion of cold fronts, and studied the upper atmosphere. Along with Matthew Maury, he produced wind charts that were valuable to ocean traders and the military. The maps were later used by Tor Bergeron during his research on air masses. While at the naval observatory, Köppen returned to research in climatology and botany.

In the mid 1880s Köppen published a map showing the relationships between temperature regions and vegetation growth. This research resulted in his first attempt at climate classification in 1900, but his early system did not receive much recognition. Subsequent work led to the development of his widely known classification scheme in 1918. The system attempted to explain vegetation distribution using temperature and precipitation data. Köppen revised the system multiple times and published his final version in 1936, although he kept editing it until his death. Despite later modification by others, the basic structure has remained intact. It continues to be one of the most commonly taught climate classification systems.

Among Köppen's other contributions are several books. *The Climate of Geological Prehistory*, which he published with Alfred Wegener in 1924, added to the Milankovitch theory, which explains Earth's glacial and interglacial periods. It was one of the first books in the field of paleoclimatology. Köppen also worked with Rudolph Geiger to publish a five-volume set called *Handbook of Climatology* between 1926 and 1940.

KÖPPEN-GEIGER CLIMATE CLASSIFICATION

The Köppen-Geiger is a system of global climate classification created by Wladimir Peter Köppen and subsequently updated and revised by Köppen in collaboration with Rudolf Geiger. It is the best-known and most widely used global climate classification available.

Köppen was born in St. Petersburg, Russia, in 1846, and died 94 years later in Austria after making a prolific contribution to science. His early training in botany appears to have exerted considerable influence on the work for which he is best remembered—a global classification of climate. In an interesting twist of fate, his daughter married Alfred Wegener, the pioneer of continental drift, with whom Köppen collaborated on global paleoclimate reconstruction; this project presumably emphasized to him the importance of a global system of climate classification. In the 1930s, Köppen collaborated with Rudolf Geiger, his junior by 48 years, in writing the *Handbuch der Klimatologie* and in updating and revising his climate classification system, which Geiger continued to work on after Köppen's death in 1940. The classification is now widely referred to as the Köppen-Geiger classification in recognition of Geiger's contributions.

In this classification, climates are divided into five major categories, designated by the first five letters of the alphabet and always capitalized (see Table 1). Subsidiary properties of the classification are also denoted by letters of the alphabet,

always in lowercase. The first major division in Köppen's system is the distinction between humid climates and dry climates. The climate zones A, C, D, and E are humid, and the arid B climates are divided into two groups using an uppercase letter—steppe (BS) or desert (BW). Within the humid climate group, distinction is made on the basis of temperature, progressing sequentially from tropical (A, mean temperature of the coldest month $\geq 18^\circ\text{C}$), to temperate (C, mean temperature of the hottest month $>10^\circ\text{C}$ and mean temperature of the coldest month between 0°C and 18°C), to cold (D, mean temperature of the hottest month $>10^\circ\text{C}$ and mean temperature of the coldest month $\leq 0^\circ\text{C}$), to polar (E, mean temperature of the warmest month $<10^\circ\text{C}$), with the E type climates also divided into two groups using an uppercase letter—ET indicating tundra and EF indicating frost climates.

The climate zones A, C, and D are further divided internally on the basis of the seasonality of rainfall using lowercase letters. No further subdivision is made in the case of the ET and EF climates. The tropical A climates are divided into f, rain forest climates, with high temperatures and rainfall all year; m, monsoon, with a dry season; and w, savanna, with the distinction between monsoon and savanna being based on the relative dryness of the dry season.

The arid (B) climates are separated from the humid climates using a dryness threshold and are then divided into steppe (BS) and desert (BW), also using the dryness threshold, which depends on the mean annual temperature and the seasonal distribution of rainfall. As in the subdivision of other climate types, an important principle is whether the most precipitation occurs during the warmer months of the year, when it will be more effective for plant growth. The dryness threshold varies depending on the seasonal distribution of rainfall. If 70% of the precipitation occurs in winter, then the dryness threshold is calculated as twice the mean annual temperature (in $^\circ\text{C}$). Where 70% of the precipitation occurs in summer, the dryness threshold is calculated as 28 plus twice the mean annual temperature. Where the seasonal concentration of precipitation is below 70% in both seasons, the dryness threshold is calculated as 14 plus twice the mean annual temperature. Summer and winter are

1st	2nd	3rd	Description	Criteria
A			Tropical	$T_{\text{cold}} \geq 18$
	f		Rain forest	$P_{\text{dry}} \geq 60$
	m		Monsoon	Not (Af) and $P_{\text{dry}} \geq 100 - \text{MAP}/25$
	w		Savanna	Not (Af) and $P_{\text{dry}} < 100 - \text{MAP}/25$
B			Arid	$\text{MAP} < 10 \times P_{\text{threshold}}$
	W		Desert	$\text{MAP} < 5 \times P_{\text{threshold}}$
	S		Steppe	$\text{MAP} \geq 5 \times P_{\text{threshold}}$
		h	– Hot	$\text{MAT} \geq 18$
		k	– Cold	$\text{MAT} < 18$
C			Temperate	$T_{\text{hot}} > 10$ and $0 < T_{\text{cold}} < 18$
	s		Dry summer	$P_{\text{sdry}} < 40$ and $P_{\text{sdry}} < P_{\text{wwet}}/3$
	w		Dry winter	$P_{\text{wdry}} < P_{\text{swet}}/10$
	f		Without dry season	Not (Cs) or (Cw)
		a	– Hot summer	$T_{\text{hot}} \geq 22$
		b	– Warm summer	Not (a) and $T_{\text{mon10}} \geq 4$
		c	– Cold summer	Not (a or b) and $1 \leq T_{\text{mon10}} < 4$
D			Cold	$T_{\text{hot}} > 10$ and $T_{\text{cold}} \leq 0$
	s		Dry summer	$P_{\text{sdry}} < 40$ and $P_{\text{sdry}} < P_{\text{wwet}}/3$
	w		Dry winter	$P_{\text{wdry}} < P_{\text{swet}}/10$
	f		Without dry season	Not (Ds) or (Dw)
		a	– Hot summer	$T_{\text{hot}} \geq 22$
		b	– Warm summer	Not (a) and $T_{\text{mon10}} \geq 4$
		c	– Cold summer	Not (a, b, or d)
		d	– Very cold winter	Not (a or b) and $T_{\text{cold}} < -38$
E			Polar	$T_{\text{hot}} < 10$
	T		Tundra	$T_{\text{hot}} > 0$
	F		Frost	$T_{\text{hot}} \leq 0$

Table 1 Description of Köppen-Geiger climate symbols and defining criteria

Source: Peel, M. C., Finlayson, B. L., & McMahon, T. A. (2007). Updated world map of the Köppen-Geiger climate classification. *Hydrology and Earth System Sciences*, 11, 1633–1644. Reprinted with permission.

Notes: MAP = mean annual precipitation; MAT = mean annual temperature; T_{hot} = temperature of the hottest month; T_{cold} = temperature of the coldest month; T_{mon10} = number of months when the temperature is above 10; P_{dry} = precipitation of the driest month; P_{sdry} = precipitation of the driest month in summer; P_{wdry} = precipitation of the driest month in winter; P_{swet} = precipitation of the wettest month in summer; P_{wwet} = precipitation of the wettest month in winter; $P_{\text{threshold}}$ = variations according to the following rules (if 70% of MAP occurs in winter, then $P_{\text{threshold}} = 2 \times \text{MAT}$; if 70% of MAP occurs in summer, then $P_{\text{threshold}} = 2 \times \text{MAT} + 28$, otherwise $P_{\text{threshold}} = 2 \times \text{MAT} + 14$). Summer (winter) is defined as the warmer (cooler) 6-month period of ONDJFM or AMJJAS.

defined as 6-month periods where summer (winter) is ONDJFM or AMJJAS.

The arid B climates are further subdivided where the letter k is used to denote that the mean annual temperature is $< 18^\circ\text{C}$ and h where the mean annual temperature is $\geq 18^\circ\text{C}$. In the C and D climates, a third letter is used to distinguish on the basis of seasonal temperature distribution. In each case, the letters a, b, and c are used to indicate hot summer, warm summer, and cold summer, respectively, and

in the case of the D climates, the letter d is used to indicate areas with very cold winters.

The most recent world map based on Köppen's classification, shown in Figure 1, was compiled using the rules set out in Table 1. The percentage of the world's land surface occupied by each main climate type is shown in Table 2. In theory, there are 30 climate types possible using this system; however, the Csc climate does not occur anywhere, and the Cwc type occupies only 0.002% of the land area.

Table 2 Percentage of the world's land area occupied by each of the main climate types

Source: Based on Peel, M. C., Finlayson, B. L., & McMahon, T. A. (2007). Updated world map of the Köppen-Geiger climate classification. *Hydrology and Earth System Sciences*, 11, 1633–1644.

Following the publication of Köppen's classification in 1918, there was a long and vigorous debate in the literature over the details of the various categories and also about the basic principles. Köppen developed his classification at a time when there were relatively few data available with which to map the world and no electronic tools to assist in analysis and mapping. It is therefore somewhat surprising that new global climate classifications produced using modern databases and computer resources

have not appeared to replace the Köppen-Geiger classification.

Both research scientists and teachers continue to use the Köppen system almost exclusively, and there have recently been two new world maps of climate using the Köppen-Geiger classification, drawn using large computer databases and sophisticated analytical methods (Kottek, Grieser, Beck, Rudolf, & Rubel, 2006; Peel, Finlayson, & McMahon, 2007). Arthur Wilcock seems to have been correct when he said in his 1968 paper,

If, on the other hand, one is convinced that there are in principle strict limits to what can be achieved by any simple classification, one may consider it profitless to seek minor improvements at the cost of confusion. (p. 13)

KROPOTKIN, PETER (1842–1921)

Peter (Pyotr) Alexeyevich Kropotkin was a leading Russian anarchist, social philosopher, explorer, and geographer. He was born and died in the Moscow region, but he traveled very widely and spent half his life in exile. As a prince in a noble family, Kropotkin was selected by Tsar Nicholas I to study in the elite Corps of Pages, a military academy for courtiers. On graduation from the Corps, bored with military science and increasingly disillusioned with the extravagance and pettiness of the Court, he volunteered to serve as an army officer in Siberia and spent 9 years exploring the region, initially as a soldier and later as a civil servant working with the Russian Geographical Society. Subsequently, he wrote extensively about

the physiography of Asia, the desiccation of extensive regions, and postglacial climatic change.

Despite his noble birth, from the age of 12 onward Kropotkin avoided using his title of prince and showed great admiration for the hard work, skills, and moral values of the common people. In European Russia, he observed the suffering of the peasants and the continuing exploitation of workers, even after the abolition of serfdom in 1861. He documented the brutal conditions endured by prisoners, peasants, and miners in Siberia; developed a passionate interest in anarchism, socialism, and communism; and read avidly about the triumphs and eventual annihilation of the Paris Commune. In 1872, he made a 3-month trip to visit the International Workingmen's Association in Switzerland and learn more about Western European experiences of revolution and social transformation. Returning to Russia, he helped build the fledgling anarchist communist movement until he was arrested and imprisoned. He escaped in 1876 and fled to England, where he spent most of the next 40 years, intermingled with shorter periods in France and Switzerland and an 1897 visit to North America. In May 1917, he returned to Russia, but he was soon marginalized by the October Revolution and Lenin's emphasis on tightly controlling political power.

Kropotkin's primary contribution to geography is his vision of an alternative future—decentralized, dispersed, integrated, and powered by renewable sources of electrical energy—and a new geography to counter the capitalist vision of globalized markets based on free trade and comparative advantage. He rejected the exploitation and alienation of labor associated with capitalist mass production, the environmental destruction associated with large-scale urbanization and the heavy use of fossil fuels and artificial fertilizers, and the enormous waste of energy associated with globalized commodity trading. Instead, he advocated the integration of manual and intellectual labor in villages and small towns, with a mixture of agriculture, handicrafts, and small industries. Local territories would be self-governing, cooperatively organized and moderately self-reliant, and loosely federated with neighboring communities and engaging in interregional trade. As well as contributing to the anarchist cause and critiques of capitalist globalization and Soviet authoritarianism,

his work strengthened the Arts and Crafts Movement and helped inspire the movements advocating garden cities, organic farming, community food security, appropriate technology, and bioregionalism. Kropotkin's close intellectual contacts included Élisée Reclus, Patrick Geddes, Ebenezer Howard, and William Morris.

KRUMMHOLZ

Krummholz, the crooked trees that are battered and stunted by harsh microclimates, exist at the upper edge of tree growth in mountains. Their name is derived from the German term for crooked or twisted wood. These krummholz, or elfin wood, suffer strong winds, low temperatures, intense radiation, and short growing seasons, and thus they become deformed. The geography of krummholz provides clues about microclimates, species' distributions, water supplies, and climate change.

Most krummholz are evergreen trees, such as the Engelmann spruce (*Picea engelmannii*); however, occasionally, deciduous trees, such as the quaking aspen (*Populus tremuloides*), will have a stunted form. In some areas (e.g., the European Alps), the dwarfed and crooked krummholz forms are genetically induced. In other areas (e.g., North America), the krummholz forms are considered

to be caused by microclimatic factors that have acted on the tree during its lifetime.

Krummbol extend from the upper edge of a noncrooked, dense forest, through a transitional zone or ecotone of increasingly crooked trees, to the treeless tundra (see first photo). Often, the ecotone appears as a belt of krummbol, paralleling the contours of a slope. The belt might be quite wide on a leeward slope, where strong, downslope winds, moving first across the tundra and carrying ice and rock particles, blast into the trees. In contrast, winds moving upslope through a forest will cause little deformation because they tend to move slower and be less abrasive.

A variety of factors affect the type and degree of stunting that occur in krummbol. Short and cool growing seasons may prevent maturation and acclimatization of tree tissues to be prepared for winter extremes. Immature tissues may not limit water loss to the dry atmosphere

through the waxy coverings or cuticles of their needles. If krummbol are not protected by snow cover during winter, they are exposed to wind-driven ice and rock crystals that can pit the tissues and accelerate evaporation. Without insulating snow cover, soil water can freeze, preventing roots from uptaking water. Intense ultraviolet radiation, especially at high elevations, can damage exposed tissues. In all these cases, the growth tissues can be killed and may fall off the tree, leaving it weakened and in a crooked and stunted form.

Forms of Krummbol

Although the forms of krummbol can be quite varied (they are as diverse as the diversity of their harsh microclimates), three forms can typically be found. The first form, the flag krummbol, is found just upslope from the symmetrical,

noncrooked trees of the dense forest. This tree is shorter in height than the forest trees, and its upper trunk has a flag form, with growth primarily on the leeward side (see second photo). During winter, ice crystals and rock particles can be bounced along the snowpack by winds and driven into the krummholz, damaging the trees' windward, exposed tissues.

The second form, the flag mat krummholz, exists upslope from the flag. Here, the winds have increased. The trunk is dwarfed, crooked, and flagged with only leeward growth (see third photo). The form includes a prostrate mat that survives beneath the winter snow. The flag mat krummholz are often widely spaced, and winds erode snow from between the trees and deposit it onto the downwind trees. This snow deposit protects parts of the krummholz from damaging winds, provides a layer of insulation against extreme air temperatures, insulates the soil, and provides protection from intense radiation.

The third krummholz form is only a prostrate mat, with no flagged, upright trunk (see fourth photo). This krummholz survives close to the ground surface, where it is most protected from the winds of the nearby tundra. These mats are often asymmetrical, with an apex-oriented upwind. Strong winds erode snow from the mat's apex, exposing it to a battering by rock and ice crystals, to low temperatures, and to intense radiation. This upwind part of the mat is also a snow fence, causing winds to deposit entrained snow on the downwind portion of the mat, insulating and protecting it. The mat survives in a larger and wider form, downwind, in response to this protection. Most mat tissues exposed above the winter snow pack are killed.

The Importance of Krummholz

Krummholz provide a great deal of information about their environment. They indicate the presence of low air temperatures, intense shortwave

The flag mat krummholz has a deformed trunk and a mat that survives when buried by snow.

Source: Author.

radiation, strong winds, frozen soils, and a short growing season. Their various forms indicate varying wind speeds, snowpack depths, growing season lengths, and both summer and winter temperatures. Snowdrifts, collecting within and downwind of krummholz, contribute meltwater to streams and lakes, long after snow packs in the forest have melted. Krummholz offer thermal cover and visual protection for animals. They provide perches for birds. Winds in the krummholz ecotone help keep mammals more insect-free during the summer months. The krummholz ecotone, with both forest and tundra plants and animals, can be seasonally biologically diverse. From tree rings, summer air temperatures can be reconstructed for the krummholz. Often, krummholz will be quite long-lived, yielding a long record.

The mat krummholz is prostrate and protected by winter snow.

Source: Author.

Finally, krummholz offer a never-ending number of unique forms that are both pleasing and perplexing to the human eye and psyche, as krummholz exist on the edge.

KUHN, WERNER (1957–)

Werner Kuhn is Professor of Geoinformatics at the University of Münster (Germany) and has been among the most active researchers in geographic information science (GIScience) for many years. Until recently, his main research interest was the semantics of spatial information, which he studies in the context of usability of geospatial data and services. He has developed several ideas and methods, including the algebraic description of semantic properties and their mappings, the derivation of ontologies from texts, and the notion of semantic

reference systems. Apart from this core subject, Werner Kuhn has carried out research in various other fields, such as visualization, engineering of geosoftware, and especially issues related to spatial cognition. Kuhn has produced a long list of internationally respected publications in scientifically leading journals, books, and proceedings.

Kuhn studied geodesy at ETH Zurich and received a diploma in surveying engineering in 1982. At ETH's Institute of Geodesy and Photogrammetry he received his PhD in 1989, with a thesis on human interaction with geographic information systems (GIS). In 1989, he was a postdoctoral research assistant at the National Center for Geographic Information and Analysis (NCGIA), department of surveying engineering, University of Maine. From 1991 to 1996, he held a position as research associate in the department of geoinformation at Vienna University of Technology, Austria. In 1995, he finished his dissertation on the semantics of geospatial information and received the *venia docendi* in GIScience from the Vienna University of Technology.

Based on his broad experience in an international context, Kuhn became a professor of geoinformatics at the Institute for Geoinformatics, University of Muenster, Germany, in 1996. Since 2003, he has held a full professorship at this institute, which was the first of its kind in Germany and introduced the first curriculum in geoinformatics as an independent subject in Europe in 1999.

Although Kuhn's early work was primarily on topological data structures and user interfaces, he turned increasingly to problems of usability of geoinformation, mainly in relationship with theories of spatial behavior, before refocusing his research group at Münster on the challenge of semantic interoperability. For this purpose, he founded MUSIL (the Muenster Semantic Interoperability Lab) in 2002. Broader areas of interest and scientific contributions are computer languages, thematic mapping, human-computer interaction, metaphors, blendings, and semantic translation.

Kuhn is an initiator of the Conference of Spatial Information Theory (COSIT) meetings, which deal with the theoretical foundations of spatial sciences and geoinformation technology. He works with colleagues who create basic theories and methods to deal with the geometric, topological, and semantic aspects of spatial information—for

example, Max Egenhofer, Barry Smith, David Mark, Andrew Frank, and others. Through these collaborations, Kuhn has become one of the main contributors to the theoretical and methodological foundations of geographical information science. Apart from the basic scientific work, he is involved in important developments that concern practical issues of geoinformation. For example, he contributed to different working groups in the Open Geospatial Consortium, served as Technical Director Europe for this organization, and has worked closely with various institutions in public administration and industry. He was also one of the founders of the Association of Geographic Information Laboratories in Europe (AGILE) and has chaired and co-organized important international conferences such as COSIT, GIScience, and AGILE.

KWAN, MEI-PO (1962–)

Mei-Po Kwan is distinguished professor of social and behavioral sciences in the department of geography at Ohio State University. She is primarily associated with the fields of geographic information systems (GIS) and urban, economic, transport, and health geography.

Kwan received a PhD in geography from the University of California at Santa Barbara in 1994. She is editor of the Methods, Models and GIS section of the *Annals of the Association of American Geographers* and has received numerous honors and awards, including the prestigious UCGIS Research Award from the University Consortium for Geographic Information Science and the Edward L. Ullman Award from the Transportation Geography Specialty Group of the Association of American Geographers.

She is an internationally recognized leader in developing and implementing GIS-based methods in research involving individual-level data (both quantitative and qualitative), three-dimensional (3D) geovisualization, geocomputation, and feminist perspectives. Her varied research programs have addressed fundamental questions about geographic methods and have influenced the development of several areas in geographic information science (GIScience) in important ways. Her work has made substantial and broad contributions to the development of innovative geographic methods, including geocomputational algorithms for implementing space-time accessibility measures that are sensitive to individual differences, 3D interactive geovisualization of complex human activity travel data, qualitative GIS and narrative analysis, the use of GIS for articulating people's emotional geographies and as an artistic medium, network-based 3D topological data models, GIS-based intelligent emergency response systems, and protection of geoprivacy through geographic masking.

Her work has focused on individuals' daily lives and the differences that gender, race, and religion can make on their experiences, mobility, and opportunities. She was the first to implement the time-geographic approach with innovative GIS-based methods on large data sets. Using geocomputation and 3D geovisualization, her work has

documented gender differences in individual accessibility that cannot be detected with conventional integral measures of accessibility or statistical approaches. This work has been expanded to take into account the impacts of information and communication technologies on people's daily activity patterns. This work has also led her to a critical engagement with feminist research methods and an ongoing process of reconciling GIS, critical geographies, and qualitative methodologies.

LABOR, GEOGRAPHY OF

Studying how people reproduce themselves materially in different places has been and remains a major preoccupation of geographical inquiry. What people do to “make a living” varies greatly across noncapitalist and capitalist economies. Economic geographers studying capitalist economies have traditionally privileged the role that capital and its institutions play in shaping the economic landscape. Labor, too simply defined as physical work done for wages, has often been reduced to a factor of production purchased along with equipment and materials to produce new commodities. Although labor quickly became the primary location factor explored by researchers, it was not considered an active agent in the transformation of economic landscapes. In the mid 1990s, however, there were calls to consider labor as an active agent shaping economic space. Most significant was Andrew Herod’s call for a new labor geography, defined as a radical approach that interprets economic space as actively produced by workers as they socially and materially reproduce themselves within systems of capitalist accumulation (although labor geographies also exist in noncapitalist societies). Since then, labor geography has emerged as a significant project within the subdiscipline of economic geography. Still, in its relative infancy, no single analytical framework has come to define or dominate labor geography as the project continues to expand and

engage in broad intellectual debates within geography and with other social sciences.

Historical Roots

There is a long intellectual history leading to the placement of labor at the center of geographical analysis. Early-20th-century geography’s dark flirtation with environmental determinism linked the ability to engage in productive work to climatic conditions. Later, rich descriptions of how people struggle to reproduce themselves by altering and adapting to their environments were central to traditional regional geography. The post–World War II quantitative revolution ushered in a scientific paradigm that attempted to mathematically model location decisions of firms by reducing labor to one of several least-cost variables; in this view, labor was not substantively different from other inputs such as land or capital.

In the 1970s, classical location theory was challenged by a new generation of radical geographers influenced by theoretical Marxism and the political events of the 1960s. These radical scholars were dissatisfied with the theoretical limits of quantitative models based in neoclassical economics. Critiques of traditional location theory challenged the abstraction of firms and workers to mere variables and argued that any discussion of the location of production must consider adversarial relations within broader capitalist processes (e.g., the labor process and

Textile industry strike in Lawrence, Massachusetts (1912)

Source: Library of Congress, LC-USZ62-98168.

industrial restructuring). Throughout the 1980s, the new conceptual position increasingly centered the labor process in analytical frameworks examining local labor market formation and patterns of (dis)investment. Local labor militancy in the face of industrial transformation was traced to the legacies of previous “layers of investment” and past struggles with capital. Discussions of regional economic restructuring at the national scale (e.g., shifts in investment from the Rust Belt to the Sunbelt in the United States) or the global scale (e.g., the rise of export processing zones) were largely in terms of the “capitalist imperative” to locate or create increasingly flexible labor markets as a response to falling rates of profit. While industrial conflict and the emergence of new labor processes became central to economic geography, explanatory accounts still remained very much focused on the power of capital to restructure economies.

Contemporary Labor Geography

The continued marginalization of workers and their institutions (e.g., trade unions) in theories of

capitalist development throughout the 1980s was perhaps to be expected. In many advanced capitalist economies, a prolonged period of neoliberal economic restructuring (in varied Reaganite and Thatcherist versions) forced organized labor into relative retreat. The evidence strongly suggested that unions were unable to improve the economic well-being of workers facing extensive labor market deregulation and deindustrialization. Instead, researchers focused on mapping and debating the primary causes of trade union decline. Yet there were a select number of studies in the late 1980s and early 1990s that began to identify how labor was responding to economic change and how such actions both enabled and challenged capital in specific locations.

In the mid 1990s, Herod was the first geographer to advocate an approach that would interpret economic landscapes from the perspective of working people, a view that noted that capitalist space is actively produced by workers and their institutions as well as by firms. The key geographical difference between capital and labor is that workers reproduce themselves in situ, while more

Congress of Industrial Organizations picketers jeering at workers who were entering a mill in Greensboro, Greene County, Georgia, 1941

Source: Library of Congress, LC-DIG-fsa-8a35773.

mobile capital is able to reproduce itself throughout the space economy. Workers are therefore forced to organize not only within specific places but across space as well. A common example cited by early labor geographers is the existence of “master collective agreements” that remove wages and working conditions from competition over large jurisdictions. Some contracts negotiated at national or even international scales influence investment decisions and regulate capital’s ability to exploit uneven economic development. The challenge, or what others have termed the *geographical dilemma*, facing workers is that there is a constant tension between workers in superior bargaining positions with capital and those with less power who are forced to undermine the “pattern” by lowering wages to attract capital to their communities. As a result, organized labor is most often limited to producing a local scale of action.

The social production of scale continues to preoccupy labor geographers, but there are subtle theoretical differences in its conceptualization and practice. Herod’s initial interest in the “scale appropriateness” of labor strategy reflects the work and influence of Neil Smith. Worker actions against capital take place at numerous scales, ranging from the microlevel (e.g., dissent through the manipulation of personal appearance or dress code), the workplace (e.g., seeking union certification), and the local (e.g., partnerships that cross class lines to attract investment) to the national (e.g., union bargaining with a large employer) and the international (e.g., the formation of union alliances across national boundaries to challenge transnational firms). Workers and their institutions will lean toward workplace, local, national, or international scales of mobilization depending on the time- and place-specific contexts.

Other labor geographers view worker organization as multiscale. Successful campaigns against capital involve simultaneous mobilization at multiple scales where workplace, community, national, and international efforts reinforce one another. For some, adopting the multiscale view still privileges labor internationalism as the most significant scale, despite the “geographical dilemma” limiting international worker solidarity (especially between workers in the global North and the global South). Other labor geographers, however, view different scales of action as nonhierarchical in nature, such as when campaigns require both local and national/international participation and call for frameworks that understand labor action as constituted by complex, interdependent relationships among workers and communities.

Apart from the scalar preoccupations of much of labor geography, there are other contributions to important debates and issues by those interested in excising the agency of workers. Specifically, there is an attempt to highlight how working people engage with social space in ways that shape their lives beyond the immediate workplace. Linda McDowell’s examination of shifting gender and race relations in postindustrial workplaces and labor markets identifies how workers are implicated in reproducing inequality. Community unions—coalitions among labor and non-labor groups for a common struggle—have also been researched by labor geographers as a means of extending the scope of study beyond immediate workplace issues. Extending the inquiry of labor geography beyond the workplace to investigate the entirety of workers’ lives will be an important future consideration for researchers.

The Future of Labor Geography

More than a decade has passed since Herod’s initial call, and although the labor geography project is still relatively new to the confines of economic geography, there has been some recent reflection on its future. Among the concerns raised are the need to extend the project to mainstream industrial relations and labor studies, questions surrounding the theorization of worker agency, and the limited empirical focus of early studies.

There have been calls to extend the conceptual tools used by labor geographers, such as the rich

theoretical understanding of the production of scale, to industrial relations. Labor geographers have engaged in broader labor studies for some time and continue to make theoretical and political contributions to labor union renewal, an extensive body of literature and practices in Anglophonic contexts. The call for multiscale approaches to organizing campaigns is very much part of this project. Discovering how new (largely urban) local initiatives such as the Justice for Janitors campaign organizing cleaners in the United States can be supported and extended to the global scale is one relevant example. Labor geographers can make normative analytical and political contributions by assessing and designing organizing strategy and public policy.

A second concern is the relatively unproblematic conceptualization of “agency” exercised by workers as they shape economic landscapes. Labor geography research is abundantly centered on advanced capitalist labor markets, as less study is focused on the global South. The concentration on established unions in mature industrial relations systems may not accurately capture the growing power asymmetries that exist between capital and workers in unorganized service sectors, immigrant labor markets, and poor economies.

Indeed, to make the labor geography project relevant for the 21st century, several new directions need to be developed. For example, some argue that labor geography may have to revisit the work of feminist geographers and seriously explore how unpaid labor shapes the economic landscape. Presently, researchers do consider the links between paid and unpaid work, but this is largely driven by the need to look more closely at the full lives of wage workers. An “unpaid labor geography” is needed that considers how social reproduction in the home and volunteering in the community shape economic space. In other words, labor geography must more fully engage with broader working-class studies, which see workers as more than “what they do to make a living” and explore the contributions workers make to political and cultural community life. Fortunately, several researchers are already beginning to strengthen labor geography by exploring these gaps in the existing research.

LAND DEGRADATION

Land degradation is one of the most important global issues because it affects all parts of the world and, more significantly, has severe impacts on agronomic productivity, the environment, food security, and the quality of life. The term *land degradation* is a relatively new scientific description of an ancient environmental problem that has been in existence probably since humans began to use fire to modify landscapes. Essentially, land degradation refers to natural and/or anthropogenic processes that substantially decrease the utility or potential utility of the biophysical environment, sometimes leading to loss or change of features of the environment that cannot be replaced. In the context of utility, land degradation results whenever there is a mismatch between land quality and land use.

This entry first discusses the definition of land degradation and explores the distinction between its proximate and ultimate causes. Though the causes of land degradation are many, the underlying fact is that it is an outcome of the mismanagement of land, which involves two interlocking, complex systems: the natural ecosystem and the human social system. Any efforts aimed at mitigating or managing land degradation or resource management must consider interactions between the two systems that will determine their success or failure. Thus, before describing particular causes, the entry examines the nature of this interaction. The entry then discusses in some detail the impact of poverty and increasing population on land degradation.

Definition and Scope of Land Degradation

Land degradation is only one of many terms that have been used to describe the process of degradation of the biophysical environment; other common references include *degeneration of the soil*, *environmental deterioration*, *exhaustion of land*, and *desertification*. The latter is often used interchangeably with land degradation, although its more appropriate usage is strictly in reference to the process of environmental degeneration

<i>Continent</i>	<i>Total Area</i>	<i>Degraded Area^a</i>	<i>Degraded (%)</i>

that occurs particularly (but not exclusively) in the arid, semiarid, and dry subhumid areas, resulting from various climatic variations and human activities. For example, the semiarid to weakly arid areas of Africa are especially vulnerable to land degradation because they are characterized by fragile soils, localized high population densities, and a low-input form of agriculture.

A universally accepted definition of land degradation may not be possible considering the many factors thought to be responsible for it. Land is considered degraded when it suffers a loss of intrinsic qualities as a result of one causative factor, to be discussed in the next section, or a combination of natural and human forces that overrun natural regeneration and/or restorative management. That is,

Net land degradation = (Natural degrading process + Human interference) – (Natural reproduction + Restorative management).

Many scholars of the environment subscribe to the general view that land degradation can occur in any part of the world irrespective of its climate, topography, or environmental characteristics so long as human demands on the natural resource base coupled with natural forces reach certain critical thresholds. Indeed, all world regions suffer from some degree of land degradation (Tables 1 and 2) that not only threatens the local quality of life but in some cases actually threatens the viability of the affected areas. As shown in Table 1, about 70% of the dry land areas worldwide have been affected by land degradation, with Africa,

Figure 1 A schematic showing some of the proximate and ultimate causes of land degradation

Asia, and the Americas having the highest percentages of degraded lands.

Causes and Processes of Land Degradation

Although land degradation has been variously attributed to “acts of God” or “acts of peasantry,” many researchers are in agreement that the problem is most widespread in environments that are exploited by humans; hence, human action takes the most blame. However, the main matrix of stability in most terrestrial environments that safeguards the land against degradation is the delicate set of reciprocal interactions between humans and factors of the biophysical environment, including climate, vegetation, soil, and topography. Any unilateral change in any

one of these components, without making the necessary adjustments for compensation so as to maintain the existing relationship, will undoubtedly result in degradation. Thus, humans alone are not responsible for land degradation. Virtually all environments from time to time suffer some kind of natural catastrophe that degrades land; some environments are especially fragile and highly susceptible to land degradation.

In most cases, it is possible to follow the processes of land degradation, but the cause(s), which could be proximate or ultimate in nature, are more complex. Figure 1 provides a schematic of some of the common causes of land degradation. The causes of land degradation are the agents that determine the rate of degradation. They could be biophysical (e.g., land use and

Picture of a severely degraded landscape due to soil erosion in the semiarid Baringo District of Kenya, East Africa

Source: Author.

land management, including deforestation and tillage methods), socioeconomic (e.g., land tenure), or political (e.g., political stability) forces that influence the effectiveness of the processes of land degradation. Proximate causes are those that are directly linked to the problem at the site of manifestation, while ultimate causes are the driving forces behind the proximate causes. Land degradation is often associated with a chain of causation that stretches away in time and space from the site of manifestation.

Understanding the cause(s) and processes of land degradation is key not only to limiting the consequences of the problem but also to its mitigation and management. Although it has long

been understood that land degradation is an environmental issue, its causes are more diverse and complex, and they cannot be explained solely by examining physical, climatic, chemical, and biological processes and their interaction. Historically, different societies have degraded their lands through one or a combination of the following processes: deforestation and habitat destruction, overgrazing, soil problems (erosion, acidification, salinization, crusting, compaction, hardsetting, leaching, and soil fertility losses), water management problems, overhunting, overfishing, the effects of introduced species, human population growth, increased per capita impact of people, and poverty (see photo).

Poverty

Poverty is an important factor that highlights the intricate complexity of these processes. It is rather obvious in many parts of the world that land degradation and economic growth, or the lack of it (poverty), are intractably linked. People living in the lower cadre of the poverty spiral are in a weak position to provide the stewardship necessary to sustain the land resource base, which in turn moves them further down the poverty spiral—setting a vicious cycle in motion. The extent of the damage inflicted on the land by any of these processes ultimately depends on environmental settings such as geology, topography, and climate, which are also regarded as natural processes of land degradation.

Increasing Population

Throughout the world, there is a diversity of environmental conditions ranging from areas with rugged topography, with dry climates and sparse vegetation cover, to areas of low relief and hot, humid climates with dense plant cover. These different environmental conditions in turn influence the soil types, the intensities of natural processes, and the stability and resilience of different terrains throughout the planet. Terrains with high potential for degradation, such as steep slopes or semiarid areas with sparse vegetation cover, are considered fragile and, therefore, highly susceptible to land degradation. In the fragile lands, energy properties (such as high relief and high rainfall or low relief and low rainfall) and materials interact with human activities to cause land degradation. The interaction is most detrimental to the natural environment where the population is high because of the enormous pressure on the natural resource base. Indeed, a rapidly growing human population is often considered the ultimate cause of land degradation; all the other causes associated with human action are only proximate causes.

Increasing population in different parts of the world is regarded as the ultimate cause of land degradation because people have been forced to adopt intensified means of agricultural production and to expand farming from prime lands onto marginal lands in order to feed their growing numbers. This observation is especially true for

poor, developing countries with fast-growing populations, where the vast majority of people are engaged in agriculture. In such countries, there is enormous pressure to increase agricultural land and to use land resources more intensively. This often results in the expansion of crop production and grazing resources onto erosion-prone landscapes such as steep hillsides, semiarid rangelands where rainfall is often unreliable and hence ill suited for continuous cropping, and semiarid and arid environments where irrigation must be used. People may also be forced to use marginal lands for reasons not directly related to increasing population, such as social unrest, monopolization of the better lands by landlords, or conversion of land into nature preserves and parks.

Exploitation of Marginal Lands

The exploitation of marginal lands results in short-term production gains that are not sustainable in the long term, resulting in severe land degradation and a decline in water supplies. Exploitation of marginal land is not necessarily a recipe for degradation—fluctuations in climate as well as changes in the availability of agricultural inputs and the outbreak of pests and diseases in these fragile landscapes expose them to the risk of degradation. Land degradation reinforces poverty, which in turn induces land degradation because poor people often opt for immediate benefits from the land, often at the expense of long-term sustainability. Although increasing human population often leads to agricultural intensification and land degradation, sometimes there are exceptional cases. For instance, in Machakos, Kenya, Mortimore, Tiffen, and Guchuki have shown that a fivefold increase in population between 1932 and 1990 resulted in better environmental management and increase in agricultural production rather than soil erosion and other forms of land degradation.

Deforestation

Population growth is often accompanied by deforestation, a term that includes processes such as loss of forest cover, woodland, and scrubland cover, which are directly linked to land degradation. Deforestation is one of the proximate causes of land degradation. The term *deforestation* is

often imprecisely used to imply quantitative loss of woody vegetation alone, yet there can also be qualitative degradation, for example, replacement of a species-rich tropical forest with a pine plantation or change to a regrowth (secondary) forest. In the tropical rain forest, the natural vegetation plays an important protective role by minimizing splash erosion, preventing the raindrops from compacting the soil, reducing runoff, and providing shade that maintains high levels of soil moisture. Deforestation in the rain forest removes the soil surface protection, thereby allowing sunlight to reach the soil. This can quickly raise the soil temperature and dry out the soil surface after a few rainless days, creating a thin, hard crust that encourages runoff and raises the potential for soil degradation. Forest degradation can alter local or regional hydrology or initiate changes in the local climate by making the climate drier due to an increase in surface water runoff and a decrease in net evapotranspiration.

LANDFILLS

Landfills represent an engineered approach to the land disposal of wastes. In many countries, landfills are the primary means for managing municipal solid wastes and other wastes such as construction and demolition debris. Specially designed landfills are used for the disposal of hazardous and even radioactive wastes. Landfills represent an improvement over the open dumps they replaced and yet create serious problems of their own, including finding suitable sites, controlling leachate and gas emissions, and long-term care and monitoring.

Waste Management History

Humans have always faced waste disposal challenges, and our understanding of past societies owes much to the refuse piles they left behind. Historically, open dumps were the preferred means of refuse disposal and were simple in operation, if inelegant in practice. Dumps fostered problems with insects, rodents, odors, and water pollution. The first sanitary landfill in the United States opened in Fresno, California, in the 1930s and is listed on the National Register of Historic Places. It was innovative because wastes were compacted and covered with soil at the end of each day. After World War II, sanitary landfills became the accepted approach to solid waste disposal. However, sanitary landfills were hardly free of problems. For example, the Fresno Landfill was added to the National Priorities Superfund List by the U.S. Environmental Protection Agency (EPA) and has undergone an extensive cleanup designed to clean up contaminated groundwater and prevent migration of dangerous landfill gases. The Fresno Landfill was not unique—many of the U.S. Superfund sites are former dumps or landfills.

The 1976 Resource Conservation and Recovery Act (RCRA) promulgated stringent waste disposal standards. RCRA Subtitle C addresses hazardous wastes and gave the U.S. EPA primary authority to oversee the permitting of facilities for their treatment, storage, and disposal. Subtitle D provides minimum nationwide standards for the disposal of nonhazardous wastes, with regulatory programs administered by state authorities. RCRA

Hazardous waste and garbage mixture in Lowry Landfill, Colorado, 1978

Source: U.S. Geological Survey.

classifies wastes as hazardous and nonhazardous based on their origin and chemical characteristics. Nonhazardous wastes include both industrial wastes and municipal solid wastes. Municipal solid wastes are generated by households and businesses. Industrial wastes include construction and demolition debris, medical waste, and special wastes, which are large-volume wastes such as mining, crude oil, and natural gas wastes that were exempted from hazardous waste regulations. With its affluent, consumer lifestyles, in 2006, the United States generated 4.6 pounds per person of solid waste each day. While landfill disposal is prioritized below waste reduction, reuse, recycling, and incineration, it remains the most commonly used technique in the United States. Although incineration reduces the volume of wastes, it still produces significant quantities of ash to be landfilled. In many cases, landfilling is the least expensive alternative. In 2006, 41% of municipal solid waste in the United States was recycled or

composted, 13% was combusted for energy recovery, and 55% went directly to landfills.

Environmental Issues at Landfills

The long-term settlement of the landfill's contents and the stability of its slopes remains an ongoing concern after closure. Wastes inside a landfill undergo biological decomposition in a process that can take years or decades. As oxygen is depleted, anaerobic decomposition produces methane and carbon dioxide—both significant greenhouse gases. Landfill gas often contains explosive levels of methane as well as volatile organic compounds, such as the carcinogens benzene and vinyl chloride. Landfill gas is produced for many years after waste disposal has ceased and can migrate off-site. Liquids in the waste and infiltrating precipitation create landfill leachate, a potent pollutant much stronger than sewage and laden with leached organic and inorganic chemicals.

Landfill Design

Under RCRA, landfills are required to prevent groundwater contamination and control gaseous emissions. RCRA forbids the construction of landfills in floodplains, wetlands, and other unsuitable areas. Local and state regulations may further restrict acceptable locations. RCRA Subtitle D (for nonhazardous wastes) specifies that landfills must have a leachate collection system and a single-layer composite liner system. A composite liner consists of a synthetic geomembrane, typically of high-density polyethylene resting on a 2-foot layer of compacted clay. Atop the liner, a leachate collection system constructed of filter soil and gravel and perforated pipes collects and conveys the leachate to a treatment system. Daily cover may consist of soil or alternatives such as polymers, spray slurries, or synthetic fabrics. Other requirements for landfill operators include groundwater monitoring, landfill gas controls, final capping, and continued monitoring and care for 30 years after closure. In addition to the requirements for nonhazardous waste landfills, Subtitle C hazardous waste landfills must have a double liner with leak detection between the liners. To control greenhouse gas emissions and recover energy, some landfills generate electricity from recovered gases.

Landfill Siting

With the implementation of more rigorous design standards, the number of landfills has decreased dramatically, and the industry has undergone concentration. The number of landfills in the United States dropped from 7,924 in 1988 to 1,754 in 2006. One of the most significant problems for landfill disposal is that of finding an acceptable site. Suitable locations must meet physiographic criteria and be politically acceptable in the eyes of local or state permitting authorities, which inevitably encounter “not in my backyard” (NIMBY) activists. Given the politicization of locational decisions, landfill sites often reflect historic land use patterns and/or the geography of least political resistance—spatial analysis suggests that low-income or minority residents are overrepresented near solid waste and hazardous waste landfills. However, a landfill for polychlorinated biphenyl

(PCB)–contaminated soil in the poor, mostly African American, Warren County, North Carolina, resulted in a protracted but eventually successful community resistance campaign that was seminal in the environmental justice movement. Suggested solutions to locational conflict include greater use of geographic information systems, more participatory decision-making processes, and shifting responsibility back to industry.

LANDFORMS

Landform is a generic term that describes the shape or form of a particular landscape. Landforms vary widely in shape and scale and are largely classified by the processes that lead to the development of each type of landform. In general, landforms are created by a combination of plate tectonics and erosion. Not only is plate tectonics responsible for producing mountains and volcanoes, but the apparent lack of tectonic activity can also lead to the formation of vast plains and low-relief landforms. No matter what the tectonic setting of a particular place may be, all landforms are directly shaped and influenced by erosion. It is the combination of the tectonic setting and the dominant type of erosion that leads to the primary classifications of landforms.

Classification of landforms is largely due to natural erosive processes, but humans have an

Nearly 370 ft. in diameter, Grand Prismatic Spring in Midway Geyser Basin is the largest hot spring in Yellowstone National Park and is considered to be the third largest in the world (New Zealand has the two largest springs). The Hayden Expedition in 1871 named this spring because of its beautiful coloration, and the artist Thomas Moran made water-color sketches depicting its rainbow-like colors. The colors begin with a deep blue center followed by a pale blue. Green algae forms beyond the shallow edge. Outside the scalloped rim, a band of yellow fades into orange. Red then marks the outer border.

Source: Mila Zinkova.

increasingly significant impact on the development and shape of the landscape. The most common natural processes develop landforms in coastal, glacial, fluvial (rivers), periglacial, *eolian* (also spelled *aeolian*), and karst areas. Landforms in all these settings are also greatly influenced by mass wasting processes such as rockfalls and landslides. Commonly, there is also a combination of processes, such as both physical and chemical weathering, that helps shape each type of landform. Also, the type of bedrock or surface material leads to the degree of resistance to erosion that each area displays. Examples of each major category of landforms are described as follows.

Volcanoes

An example of the complexity of landforms can be found in the processes that develop volcanoes and volcanic landforms. The tectonic setting determines the chemistry of the lavas and largely the shape of the ensuing volcano. Along colliding ocean plates or ocean and continental plate subduction zones, composite volcanoes are formed, which are often cone shaped and produced by a combination of variably explosive and flowing types of eruption. The classic example of the type of tectonic setting containing composite volcanoes can be found in the Cascade Range in the United States, with Mount St. Helens perhaps

Figure 1 Map of the Yellowstone caldera

Source: U.S. Geological Survey.

being the most famous volcano. The chemistry of hot spot volcanoes, such as those found on the Big Island of Hawaii, is very different from that of composite volcanoes, and the flowing eruptions most often produce large, low-angled, shield-type volcanoes when the hot spot occurs within ocean plates. Hot spots that develop within continental plates can produce subtle volcanoes such as the Yellowstone (Figure 1) or the Long Valley Caldera in California. These landforms do not look like the classic volcano but are capable of producing tremendous climate-changing eruptions and large-scale landforms such as calderas and pyroclastic deposits that can cover large

areas. The chemistry of rift zone volcanism produces flowing eruptions, which often flow over and cover large swaths of land. An example of rift zone volcanics in the United States can be found within the large basalt flows of the Columbia River Basalt Province.

Once a landform is created, its location and size largely determine what types of erosive processes will continue to shape that landform. The Hawaiian island volcanic chain is largely shaped by a complex interaction of processes, including coastal, fluvial, and mass wasting activity. The Cascades are influenced by glacial, fluvial, and mass wasting processes, and the Columbia Basalts

are more heavily carved by fluvial erosion. The coastlines of the Hawaiian Islands are greatly influenced by wave action, which produces landforms similar to other emergent coastal locations. The slopes of the volcanoes are shaped by excessive amounts of rain water that concentrates in streams and through time carves the deep valleys that help make the islands famous. These fluvial processes are much more complex than elucidated here. For example, the porous nature of the volcanic bedrock allows water to flow subsurface from one drainage area to another. Through time, these preferential drainages are eroded into large, U-shaped valleys. These valleys are particularly prominent in the wetter areas of the older islands, such as Kauai, Oahu, and Molokai.

Mass wasting processes on the Hawaiian Islands also are complex and vary widely in spatial and temporal scales. For example, small-scale landslides are common in the steeper parts of the islands and are often induced by heavy rain. However, on occasion, very large landslides will slough off the sides of the islands with devastating results. These failures contain many cubic kilometers of material and are transported miles offshore. These landslides greatly reshape the islands, from the broad gentle slopes of the shield volcanoes to the steep, impressive coastlines that are present today. Fortunately, none of these large-scale mass wasting events has occurred in historic times.

Landform Formation and Sculpting Processes

Landforms can also be defined and described based on the formation processes (primarily tectonics) and sculpting processes (primarily erosion) that shape Earth's surface. The truly intricate interactions between these processes are too complex for this entry and in many cases are still poorly understood. Again, examples primarily from the United States will be used.

The landforms found along the Atlantic and Pacific coastlines of the United States are dramatically different. This is largely due to the differences in the tectonic setting. The tectonically active West Coast has a coastline that is emerging from the Pacific Ocean, and the landforms reflect the generally steep nature of the Pacific Coast. In contrast, the Atlantic Coast is tectonically passive, and the landforms along that coast reflect a

coastline that is slowly subsiding through time. Emergent coasts have characteristically steep cliffs that are shaped by wave action. Waves that strike the Pacific Coast are often larger due to the westerly wind direction and the great expanse of the Pacific. These waves carve the coast into landforms such as marine cliffs, sea arches, sea stacks, and wave cut platforms. Beaches along the Pacific Coast are often small (if they can be found at all) and are bounded by steep cliffs, making public access difficult. If tectonic uplift continues along the Pacific Coast, the wave cut platforms are often uplifted to become marine terraces. In California, these terraces can often be seen in series.

The Atlantic Coast of the United States is dominated by a low-angle coastline with characteristic broad sandy beaches, large estuaries, offshore barrier islands, and brackish-water sounds that separate the islands from the mainland. The beaches of the Atlantic coast characteristically have distinct features shaped by waves, currents, and wind. Beginning offshore and traveling inland, the beach features include longshore bars, longshore troughs, the beach, a wave cut berm, and backshore beach dunes deposited by waves and wind.

Landforms created by glaciers can largely be separated into those caused through erosion by glacial ice and those created by deposition of the eroded material. Again, the tectonic setting greatly influences the type of glacier and the landforms that develop. In tectonically active areas, primarily mountains, alpine or valley glaciers dominate, while in tectonically inactive areas, primarily plains, continental glaciers have the greatest influence. Landforms created by erosion vary greatly between alpine and continental glaciers. Alpine glaciers are responsible for creating much of the high mountain landscapes that people find so breathtaking and beautiful. Alpine glacial landforms are numerous and include arêtes, cols, cirques, horns, hanging valleys, truncated spurs, glacial troughs (the classic U-shaped glacial valleys—fjords if inundated by seawater), tarns, paternoster lakes, and roches moutonnées. Depositional landforms include terminal, lateral, recessional, and ground moraines; glacial erratic; and the features found within the outwash plain of the glaciers.

Continental glacial landforms are often more subdued because of the lower relief of the

landscape but also much larger in scale because of the continental size of the glaciers. Continental glaciers scoured the basins that now hold the Great Lakes of North America, with Lake Superior having the greatest surface area of any freshwater lake in the world. Other features, including kettle lakes and prairie potholes, are formed by a complex process of stagnant ice deposits, which create depressions in glacial debris that later fill with water as the ice melts. Depositional landforms created by continental ice include eskers, kames, drumlins, and a variety of moraine landforms: terminal, lateral, medial, recessional, and ground moraines. Some of these depositional features, such as the drumlin “Bunker Hill” in Boston, Massachusetts, have a very important influence on the history of the United States.

Landforms created by rivers are quite numerous and complex. Again, they can be related to tectonics in that high-relief fluvial landforms are distinctly different from those that develop on low-slope topography. High-relief landforms tend to be erosional, while low-relief landforms tend to be a combination of depositional and erosional landforms. Erosional processes remove material, while depositional processes produce landforms by depositing the material eroded upstream. As with most other landforms, fluvial landforms are dynamic. They often change rapidly, primarily during floods, thus possibly making them the most important landforms in terms of hazards to humans and their infrastructure. Streams and rivers produce distinct patterns on the land. The most common drainage pattern is the dendritic, with trellis, radial, and glacial also being fairly common. High- to moderate-relief fluvial landforms include ravines and canyons, which differ due to age and the volume of water creating the landform. These also often contain rapids and waterfalls created by the differing resistance of the underlying bedrock. Low-slope-angle landforms include the river channel or thalweg, levees, and floodplains. Low-slope rivers also will often meander, which creates point bar deposits, cut banks, and oxbow lakes. The tectonic setting and wave action will determine the type of landform that develops when the river enters the ocean. In oceans with mild wave action, deltas will develop, while in subsiding or sinking coasts, estuaries are a common feature.

Karst, Periglacial, and Eolian Landforms

Karst landforms are named for a region in Slovenia and involve landforms that develop in limestone. These landforms are numerous and often have duplicate names in a variety of languages. Caves are the most common karst features, with their attendant landforms stalactites, stalagmites, columns, draperies, and other dripstone formations. Other landforms include sinkholes, dolines, and tower karsts. The latter can be spectacular and are often the subject of artistic paintings and the background for movies.

Periglacial landforms are climatically driven. These develop in cold, dry climates and are primarily the result of freezing and thawing activity. In Arctic conditions, ice or sand wedges can develop, as well as pingos, solifluction lobes, and thermokarst if the permafrost melts and produces a basin filled with water. Other common landforms include sorted and unsorted patterned ground. These patterns can develop into circles, polygons, nets, and stripes depending on the increasing slope angle. Other landforms include felsenmeer (sea of rocks), and some authors include nivation hollows among the periglacial landforms.

Eolian landforms are landforms produced by wind. These landforms are largely depositional, with the exception of blowouts and yardangs, which involve the removal of material, and ventifacts, which are rocks and boulders that are scoured and shaped by blowing sand. Sand dunes are the most common type of eolian landform and include a variety of different types, including Barchan, parabolic, star, seif, and longitudinal dunes. Some of the most spectacular landscapes in North America, such as the Zion and Canyonlands National Parks, were produced when ancient sand dunes were buried, lithified, and subsequently reexposed by fluvial erosion.

The Role of Scale

The importance of scale was mentioned earlier in this entry. A thorough discussion of variations in scale (such as micro, meso, macro, mega) among all landforms is beyond the scope of this entry; however, a brief discussion of the complexities of scale and the concept of polygenetic processes will

Some of the most spectacular landscapes in North America, such as Canyonlands National Park, Utah, were produced when ancient sand dunes were buried, lithified, and subsequently reexposed by fluvial erosion.

Source: U.S. Geological Survey.

be instructive. Polygenetic processes involve different processes, for example, freeze-thaw versus wetting and drying, which produce similar looking landforms. Similarly, a single process, for example, freeze-thaw, can lead to completely different landforms. A good example of the combination of scale and polygenetic processes can be found within sorted periglacial patterned ground in midlatitude high-mountain environments such as the White Mountains of California. Above 3,900 m (meters), large-scale (macroscale) sorted polygons are relatively common. These polygons average around 5 m in width and are bordered by boulders weighing around 50 to 100 kg (kilograms). These landforms most likely developed in a permafrost environment and are no longer active in the present climate. However, contained within the central area of fines within the large-scale sorted borders are numerous active small-scale (mesoscale) sorted polygons. These 1- to 2-m

landforms are bordered by stones weighing 2 to 5 kg and are produced by yearly freeze-thaw cycles. Contained within the mesoscale polygons and expressed on the surface of the central area of fines are microscale polygons that develop sorted borders composed of gravel and pebbles. The production of microscale landforms is through a combination of diurnal needle ice processes and the wetting and drying of the soil. The drying process opens desiccation cracks and actively sorts the gravels. Each scale of these sorted polygons involves sorted patterns, but each is created by a combination of different (polygenetic) processes.

Anthropogenic Influences

Humans have become the dominant geomorphic agent on Earth, and human activity now moves more material than all the rivers, glaciers, wind, and oceans combined. Human landforms can be

subtle or quite visible from space. Subtle landscapes include enhanced levees, floodwalls, breakwaters, groins, jetties, and even the leveling of land for construction or, more important, agriculture. Flying over almost any landscape other than the oceans reveals a distinct and obvious human imprint on the land. Other human landforms are not as subtle. These include but are not limited to open pit mines, excavation pits for construction projects, and quarries. Human activity primarily affects our coasts, plains, and rivers, but it also affects glacial, periglacial, eolian, and karst landforms. For example, the development and placement of a road will affect numerous landforms and in many cases disrupt the natural landform-creating processes. Human activity will continue to shape the Earth, and human landforms will continue to be a dominant feature of Earth's landscapes, particularly in the lower to moderate latitudes.

LAND REFORM

Land reform entails the redistribution of private or public lands. Though it is often broadly associated with struggles for social justice, land reform is a somewhat amorphous term, embracing a huge range of practices and historical experiences in how land is identified and transferred (by force, legislation, or markets), the accompanying institutional and legal changes, and the ensuing property relations. Though many industrialized countries have highly unequal distributions of land, land reform is typically discussed in the context of the developing world.

Colonial Antecedents

The challenges and struggles associated with land reform have extensive historical roots in the colonial period. For the rural poor in developing countries, two of the most debilitating legacies of European colonialism were the establishment of uneven landscapes and commodity export-dependent economies, which went, and continue to go, hand in hand. In a broad sense, colonialism both magnified and hardened the inequalities where they already existed (in tributary or feudal societies) or established highly unequal distributions of land, for instance, as extensive export-oriented plantations took over the best agricultural land and as more successful small- and medium-scale farmers expanded within the increasingly competitive economic systems.

Most of the wealth generated by export commodities such as sugar, coffee, tea, palm oil, cocoa, cotton, and tobacco flowed back to Europe or was concentrated in the hands of a relatively small number of large farmers and merchants. At the same time, import dependence on a diverse range of manufactured goods and services became deeply entrenched. This position within international trading networks has proven to be extremely durable for the world's poorest nations, whose export structures are still predominantly based on a small number of mostly low-value commodities with often highly volatile prices in world markets.

Land Inequality

Land inequality is closely associated with poverty and hunger in many places. Land inequality also has a marked gendered character. On a global scale, according to the Food and Agriculture Organization (FAO) of the United Nations, women make up 51% of the total agricultural labor force, with especially high levels in the world's poorest countries, but almost everywhere, women's rates of land ownership pale in comparison with their contribution to agricultural production. Geographically, land inequalities are especially marked throughout most of Latin America, the Caribbean, and Southern Africa, as well as large parts of South Asia and East Africa. In Latin America and the Caribbean, the world's most inequitable region according to a recent United Nations report, 75% of the total agricultural population has access to only 10% of all arable land. At the extreme end of the spectrum, in nations such as Brazil, Guatemala, and Jamaica, a very small percentage of all landholders control more than half of all arable land—an inequality that is magnified by differences in land quality.

In short, the widespread persistence of land inequalities is one starting point for contextualizing challenges and debates associated with land reform. Another key starting point, related somewhat conversely, is the explosiveness of land inequalities in igniting social struggle. In the first half of the 20th century, land inequalities played a central role in inciting major revolutionary struggles in Mexico, Russia, and China, with different processes of land reform ensuing in each case. The land reform following the Chinese Revolution has been described as the largest appropriation and redistribution of property in world history, taking land away from a powerful nobility and transforming it into village collectives.

The Post–World War II Period

The powerful ideological and material implications of land reform were in plain view in the rapid process of decolonization that followed World War II. On the one hand, strong international laws were established to protect the private property relations wrought by colonialism. On the other hand, nearly half of humanity lived in countries

undertaking land reform in the late 1940s. In the subsequent decades, land reform was greatly influenced by escalating Cold War tensions.

While the idea of appropriating large holdings may have resonated strongly with many small farmers and landless workers, collectivization was often viewed with suspicion (if not outright fear) by small farmers. Small farmers were thus frequently seen as a potential bulwark against revolution. In some instances, this brought them little more than anticommunist propaganda, but in other instances, significant private property-based land reforms accompanied attempts to diffuse or keep revolutionary pressures out of the countryside.

For the West, land reform had special importance in East Asia after World War II, with fears of the peasant-led Chinese Revolution both most recent and most proximate. The United States had an important role in encouraging significant redistributive land reforms in Japan, South Korea, and Taiwan, with the hope of creating modest-sized capitalist farmers and mitigating more radical social pressures for transformation. These reforms, which were based on producing for domestic rather than export markets and were supported by things such as extension services, subsidized credit, and protective trade barriers, became widely cited as examples of how state-supported capitalist land reforms can generate significant gains in agricultural output, income distribution, and the diversification of rural economies.

The quick and notable successes of the East Asian land reforms emboldened the case for developmental states to facilitate some degree of redistributive land reform to the rural poor. In the eyes of Keynesian economists and planners, this held the prospect of multiple benefits: enhanced food access and employment and income generation for the poorest segments of rural society; more broadly distributed income, savings, and capital available for investment; and increased demand for farm inputs and nonfarm goods and services.

The 1970s

Prominent development economists began drawing attention to evidence of an inverse relationship between farm size and output per unit area

in the 1970s. That is, while yields might be greater on high-input monocultures, small- and medium-sized farms were found to be more productive per unit of land than large estates, even though large farms generally controlled the best-quality land and had greater access to inputs, irrigation, and credit. A key explanation was that small farms have more diverse and intensive cropping patterns than do large farms, made possible by greater labor intensity, as labor inputs generally drop off quickly as farm size expands.

Unfortunately, gender relations were a severely underappreciated dimension of land reform, and insufficient attention was given to how male-centered land titling processes regularly eroded the customary rights held by women, exacerbated the uneven household divisions of labor and decision-making power, and excluded the female heads of households. A detailed FAO report in 1995 described the dismal gender record in blunt terms, noting that they have rarely worked to women's benefit.

Barriers to Reform Emerge

While Keynesian development theorizing legitimized a private property-based and patriarchal form of land reform "from above," land reform also carried more radical connotations wherever land struggles were welling up "from below" against powerful landowning elites and the interests of foreign companies. This was especially true in Latin America. There, the U.S.-backed land reforms under the "Alliance for Progress" barely dented the region's famous "latifundia-minifundia" (large holder/small holder) divide, while land struggles from below became conflated with Cold War tensions, and the activists routinely found themselves pitted against not only large landholders but also authoritarian governments backed by external political and military support.

Another powerful barrier to land reform was the rise of the input-intensive techniques associated with the Green Revolution. The Green Revolution brought celebrated gains in yield and aggregate production, but it also became notorious for acting as a land reform in reverse, as many poor farmers took on unsustainable debt loads and ended up losing their land to an emerging

class of successful commercial farmers. The dynamics of dislocation and consolidation in countries such as India were also highly gendered.

Land reform was further debilitated by the onset of balance-of-payments crises and heavy levels of state indebtedness across much of the global South in the 1980s, which precipitated the policy prescriptions of the International Monetary Fund and World Bank, known as structural adjustment programs. According to the neoliberal economic logic of structural adjustment, export growth according to a nation's comparative advantage is necessary to resolve balance-of-payments problems, with distributional equity peripheral to macroeconomic growth. In agriculture, this meant that commodity production was encouraged either in the ruts carved by colonialism or in the new, "nontraditional" sectors, which tended to invigorate large-scale farms. At the same time, both ideological and fiscal pressures called for drastically reduced state support for small farmers, in realms such as extension, research, and marketing, while land reform was largely pushed off the policy agenda altogether amid the widening social inequalities associated with adjustment.

Rekindling of Land Struggles in the 1990s

Following the repression waged against land struggles, the land reform in reverse of the Green Revolution, and the policy dictates of structural adjustment, action on land reform reached a low point in the 1980s. However, since then there has been a resurgence of land struggles and rural social movements. The most prominent example of this resurgence is the Landless Workers' Movement (Movimento Sem Terra [MST]) in Brazil, which has taken land reform into its own hands within one of the world's most unequal agrarian landscapes, coordinating the occupation and cultivation of millions of hectares of unused or underused large holdings. Founded in 1985, MST is the largest social movement in Latin America, with an estimated 1.5 landless members. In addition to land reform, MST has established cooperative farms; constructed houses, schools for children and adults, and clinics; and promoted indigenous cultures, a healthy and sustainable environment, and gender equality. In Brazil, fewer

than 2% of landowners control 46.8% of the arable land.

There has also been increasing awareness by rural social movements about the need not only to work at local or national scales but also to build coalitions across borders to better confront the powerful multilateral institutions and corporate actors that dominate the global food economy. The great manifestation of this is La Via Campesina, which describes itself as the international movement of peasants, small- and medium-sized producers, the landless, rural women, indigenous people, rural youth, and agricultural workers. For La Via Campesina, land reform remains at the crux of building more equitable and sustainable rural economies.

The rekindling of latent land struggles helped push land reform back into mainstream development policy debates in the 1990s. One of the most notable sites for the renewal of these debates has been the World Bank, where some development economists—largely ignored through the adjustment era—had been advocating land reform since the 1970s based on empirical evidence of the inverse farm size/productivity relationship. In practice, the World Bank has supported nonconfrontational, market-based reforms, which are principally a set of policies and institutional changes to make land markets more effective with respect to things such as land taxation, the costs of land transactions, and access to capital. Evidence from countries such as Brazil, Colombia, Cambodia, the Philippines, South Africa, and Thailand suggests that market-based land reform has not encouraged land transfers from large holders to smallholders, or

Members of Brazil's Landless Workers Movement (MST) march alongside the financial center of Paulista Avenue in São Paulo, Brazil, on August 12, 2009, as part of national daily demonstrations held until August 21 asking for more efforts on agrarian reform by the federal government.

significantly reduced levels of land inequality. Rather, it has at best tended to benefit a middle stratum of commercialized farmers, and at worst, it has had badly regressive outcomes, leaving out smallholders and landless people entirely.

Conclusion

Land reform policies pursued “from above” remain very different from the sort of land reform demanded—and sometimes claimed—by movements pushing “from below.” For land reform to improve the circumstances of landless people and small farmers, the strength of the latter is crucial. But even effective land reform is no panacea. Rather, it is a crucial step toward building more equitable and sustainable rural landscapes, reducing rural poverty, and enhancing food security in many parts of the world. To transform and invigorate rural economies, land reform must be accompanied by institutional supports for small farmers in areas such as appropriate inputs and technology, infrastructure, credit, extension, marketing, and gender equity legislation, with the term *agrarian reform* distinguishing these more comprehensive changes.

LANDSCAPE AND WILDLIFE CONSERVATION

Many geographers study the relationships between patterns of habitat variation and the processes through which wildlife species occupy landscapes. An animal's capacity to move across landscapes is a function of both intrinsic factors related to its behavior and physiology and extrinsic factors arising from the distribution of suitable habitat in space and time. Understanding how animals move between habitats across landscapes is important in applied contexts, especially wildlife management and conservation, and theoretical contexts, including evolutionary ecology.

Research on Wildlife-Landscape Interactions

Ecologists have studied wildlife ecology and habitat use for decades. Before the 1970s, most studies of wildlife ecology were not spatially explicit but simply categorized wildlife observations by habitat type, not location. This approach reflected the traditional emphasis in biological ecology on evolutionary processes rather than on spatiotemporal patterns. However, beginning in the late 1960s, theoretical and technological developments helped increase attention to the relationships between process and pattern. First, the theory of island biogeography, published in 1967 by the biologists Robert MacArthur and E. O. Wilson, proposed that an island's size and proximity to other landmasses was a robust predictor of the number of species in, and other characteristics of, the island's biota. Subsequently, other researchers showed that habitats that are not islands but occur in scattered, discrete patches—such as areas of alpine tundra surrounded by montane forest—are analogous to islands in how their size and spatial arrangement affect the distribution of species across landscapes. Second, in the 1980s, the field of landscape ecology flourished with the development of *patch mosaic theory*, which posits that landscapes consist of a variegated pattern (or *mosaic*) of areas (or *habitat patches*) having distinct environmental conditions. Landscapes change because conditions in

the habitat patches fluctuate through time, a process called *patch dynamics*. Finally, during the 1990s, the development and increased availability of geographic information system (GIS) software and the global positioning system (GPS) decreased the cost and increased the feasibility of spatially explicit wildlife research.

Also, since the 1970s, studies of wildlife-landscape interaction have become more prominent due to a growing concern with human-caused environmental change. Organisms respond to environmental change—whether cyclic, long term, or rapid—by migrating from habitat patches where conditions have become unsuitable to those where conditions remain, or have become, suitable. Researchers can develop conservation strategies by analyzing habitat spatiality and patch dynamics, including human disturbance, with regard to the behavior and physiology of particular species.

Wildlife species vary enormously in terms of behavior and physiology, but five factors are important in determining how patch dynamics affect a particular species. First, an animal's size is a basic determinant of habitat requirements; larger animals need larger habitat patches. Second, animals vary in the specificity of their habitat requirements, between *specialists* that can tolerate only the range of environmental conditions in a specific habitat type and *generalists* that can tolerate environmental conditions in a broad range of habitats. Habitat specificity greatly influences a species' ability to move between patches. For instance, deforestation in the Amazon often isolates birds in remnant forest patches because they are unable to cross even narrow clearings. Third, animals vary in mobility between sedentary and vagile (ability to move long distances). Fourth, animals vary in territoriality, between those that aggressively defend a particular area from other individuals of the same species and those that do not. If the habitat patch occupied by an individual in a highly territorial species becomes unsuitable, the animal may perish if nearby, suitable patches are already occupied. Finally, every species is unique ecologically, so that specific patch dynamics in a particular time and place may differently affect similar species. For example, gorillas and chimpanzees in Gabon's rain forests respond differently to human

disturbance because human activities produce patches of plants that gorillas eat but decrease the abundance of chimpanzee food plants. While these behavioral and physiological factors may be correlated—for instance, many generalists are highly vagile—they are distinct and must be considered individually.

Applications to Resource Management and Conservation

Most studies in the geography of wildlife-landscape interaction have intended to inform resource management and conservation efforts. Three main themes have emerged. First, biogeographers have sought to identify spatial configurations of habitat that are optimal for protecting particular species or conserving the largest possible range of biodiversity. Key concepts in this research relate to the size, connectivity, and shape of protected areas. In 1975, the biogeographer Jared Diamond proposed that a single large protected area would protect a greater number of species rather than several small protected areas, based on island biogeographic theory. While this idea remains debated, it has influenced many conservation efforts. Island biogeographic theory also led to the idea of *habitat corridors*, or strips of land that allow animals to move between disconnected habitat patches. Corridor effectiveness depends heavily on a species' behavior and physiology. More broadly, a protected area's shape determines its effectiveness in protecting particular species. For instance, sedentary or territorial animals may be unable to move far enough to locate sufficient habitat in long, narrow protected areas.

Second, biogeographers have sought to identify optimal approaches to protecting particular species through the analysis of species ecology and habitat spatiality. Conservation efforts may include site-specific approaches that protect particular habitat patches and species-specific approaches that provide protection to a species regardless of location. Usually, site-specific approaches are more effective for sedentary species or habitat specialists, while species-specific approaches are better for vagile species and habitat generalists. Computer-based modeling has become increasingly important in evaluating the potential effectiveness of different conservation

approaches in the context of global and local environmental changes.

Finally, nature-society geographers have shown that human-wildlife conflict often results from variation in habitat distribution in space and time. Human-wildlife conflict frequently occurs if both people and animals seek to use a habitat patch. Interspecific competition increases as the number of available habitat patches decreases. Notably, in many landscapes, humans unintentionally create habitat patches in locations where, or at times when, few other patches are available for wildlife. Thus, human-wildlife conflict may occur frequently in human-created habitats, such as fields or gardens. For example, chimpanzees in Uganda raid crops most commonly during periods when food is scarce in adjacent forest patches.

LANDSCAPE ARCHITECTURE

Landscape architecture is an academic discipline and an area of professional practice that seemingly defies definition. Demarcating the field is a difficult endeavor since the breadth of the field is quite wide, dynamic, and far ranging. This piece focuses on landscape architecture in the United States and Canada (although landscape architecture is alive and well in the rest of the world). However, in the United States, the education of a landscape architect focuses primarily on North American and European studies. This persistence is unfortunate, as few students learn much more than a brief history of landscape architecture in a history survey course akin to the European Grand Tour of the 18th and 19th centuries. A broader, transdisciplinary approach is gaining a foothold, however, producing some promising results in terms of producing more collaborative and multidisciplinary savvy landscape architects. The purpose here is to provide a means by which one can begin to see the wealth of research and practice in which landscape architects have been engaged since landscape architecture gained its professional standing in the late 1800s.

There are numerous similarities between landscape architecture and geography. Geography is generally divided into two areas, physical and human; unfortunately, these two domains are often considered oppositional. The same problem occurs in landscape architecture, which is similarly organized into two broad arenas, the physical and the human; now—as is also the case in geography—a third arena has emerged, geographic information systems (GIS) and other technologies. The field of landscape architecture is also divided in other ways, between academicians and practitioners, designers and nondesigners, and technicians and artists. Such divisions are not always constructive, though they do help differentiate the multiple focuses of the everyday work of a landscape architect. This entry provides a broad sense of landscape architecture: how it is defined; its history and theory, education and professional practice; and the current state of the field.

Definitions

The American Society of Landscape Architects (ASLA), the United States' professional association, defines landscape architecture as a

profession which applies artistic and scientific principles to the research, planning, design and management of both natural and built environments. Practitioners of this profession apply creative and technical skills and scientific, cultural and political knowledge in the planned arrangement of natural and constructed elements on the land with a concern for the stewardship and conservation of natural, constructed and human resources. The resulting environments shall serve useful, aesthetic, safe and enjoyable purposes. (www.kansas.net/~tjhittle/ladef.htm)

The Canadian Society of Landscape Architects offers the following: "Landscape architecture is (the profession) committed to the creation of meaningful and vital outdoor places and to the sustainable management of our environment." Most important, "Landscape architects strive to establish a balance between our use and enjoyment of the land with the conservation and health of the environment." And, finally, "Landscape architects are committed to improving our quality of life by applying creative, technical, and scientific skills to manage and create environments that are attractive, functional, innovative and appropriate." Landscape architects are thus involved in the design, planning, and management of a wide range of spaces, including parks and open space, academic campuses, and residential estates; they are also involved in developing civic infrastructure, in historic preservation and restoration, and in the reclamation of degraded landscapes (e.g., brownfields, extractive industry sites).

History and Theory

"What, then, should the term landscape architecture be taken to mean? It will be understood here to mean the art—or the science, if preferred—of arranging land, together with the spaces and objects upon it, for safe, efficient, healthful, pleasant human use" (Newton, 1971, p. xxi).

One of the first and foremost contemporary comprehensive histories of landscape architecture was produced by Norman Newton in his book *Design on the Land: The Development of Landscape Architecture*, published in 1971. Newton clearly articulated the transformation of a profession from garden design, a largely private endeavor, to landscape architecture as a public service. Another classic book, by Geoffrey and Susan Jellicoe, *The Landscape of Man: Shaping the Environment From Prehistory to the Present Day* (published in 1975; third edition published in 1995), covers landscape to the early 1990s. These volumes offer an inclusive and legible history of the built environment and provide concise descriptions and abundant plans, illustrations, and photographs of gardens and built landscapes from early civilization to the evolution of the modern landscape.

Landscape architecture is firmly rooted in garden design and landscape gardening, despite the fact that this association is still uncomfortable for many in the profession today—a denial of the profession's roots in the garden and a fear of the feminine in the profession, which is still primarily white, male, and upper middle class. Garden design was not, though, given the same historical and theoretical attention as architecture, even though Vitruvius mentions gardens and design in *The Ten Books on Architecture*. Yet it was not until the 18th century that in-depth attention was given to the history of gardens/gardening. The term *landscape gardener* came into usage in the late 1700s, when Humphrey Repton used the term as a professional title. Lancelot Brown is probably the most well-known of the "landscape gardeners," and it was during the 19th century that the term came to be used for those who designed and built gardens (and other landscapes). John Loudon, an English garden designer, published his *Encyclopedia of Gardening* in 1822; this was one of the first illustrated histories of gardens and paved the way for the late-19th- and early-20th-century fascination with the history of the garden.

The term *landscape architect* was first adopted by Frederick Law Olmsted, in 1863, as a professional title. Olmsted learned of this term from his mentor Andrew Jackson Downing (who, in turn, had borrowed the term from Loudon) and shifted its emphasis to the relationship between landscape and the built environment. New York City's

Central Park epitomized this new direction, as it focused on a landscape as both scenery and setting in an urban environment. The term *landscape architect* is often attributed to Patrick Geddes (1854–1932), a Scottish botanist who made unique connections between garden design, public park design, and town and regional planning. Geddes is known as one of the founders of modern town and regional planning, influencing Lewis Mumford, Christopher Tunnard, and others who had a profound impact on 20th-century urban planning. The term *landscape architect* became established as a professional title by the founding, in 1899, of the ASLA. More widespread use and knowledge of the term came with the founding, in 1948, of the International Federation of Landscape Architects. *Landscape Architecture Magazine*, ASLA's flagship journal, was first published in 1910. A brief review reveals the particular practices that predominated in certain eras.

Public parks (as well as residential estate design and planning) have long been a mainstay of the profession. Galen Cranz's *The Politics of Park Design. A History of Urban Parks in America*, published in 1982, provides a means by which to understand the changing physical design and social purpose of parks from the late 18th century through the mid 20th century. Cranz describes four eras of park design and planning: (1) the pleasure ground (1850–1900), (2) the reform park (1900–1930), (3) the recreation facility (1930–1965), and (4) the open space system (1965 and beyond). The profession grappled with the question of the 21st-century park in the late 1980s via the competition for Parc de La Villette (Paris).

During the second and third decades of the 1900s, landscape architecture began to have a profound influence on the American landscape, from national parks to larger-scale public works projects (e.g., parkways and dams). The 1930s and 1940s were the halcyon years of modern landscape architecture. It was during this time that the profession grew in its focus to include new towns, the further investigation of housing (residential estates and suburban development), campus design, and the design and planning of state, regional, and transregional roads and highways. The publication of Ian McHarg's book *Design With Nature* in 1969 marked the height of a new era of ecological design. McHarg introduced what

is now considered a classic form of landscape analysis. His book provided step-by-step instructions for the planning of human settlements that would reverse the existing pattern of destructive development practices. Ann Spirn, one of McHarg's students, produced what has become another classic in landscape architecture and planning, *The Granite Garden*, in 1984, which called attention to the importance of the profession in making and maintaining the urban landscape.

In the 1990s, the profession turned its attention to the radical changes in urban, suburban, and rural landscapes. Greenways and brownfields were the sites of experimentation for this new interest in the repair and restoration of damaged sites and toward more productive use of marginal landscapes. The 1990s and 2000s saw a renewed interest in housing, representation, and the relationship between art and landscape. New technologies (e.g., AutoCAD, Photoshop, Maya) presented new opportunities for visualizing and presenting design ideas. Residential work in the late 1980s and 1990s fluctuated between the new "estate era" and work in new urbanist ventures. Also, the 1980s ushered in an era of urban park renovation as people returned to city centers. Since the 1960s, a large part of this profession has been devoted to international work, with large-resort development continuing to account for a majority of this type of work.

According to the U.S. Department of Labor, Bureau of Labor Statistics, landscape architects held about 26,700 jobs in 2008. About 51% of landscape architects were employed in architectural, engineering, and related services. State and local governments employed approximately 6%. About 21% of landscape architects were self-employed. The job outlook for the profession is healthy, given that employment is expected to increase; this expected growth is attributed to a growing need for the profession's expertise in urban areas because of the growing population and the public's desire for more attractive public spaces. Also, the profession has increasing value particularly in an American landscape where there is an increased need for sustainable design and planning (e.g., storm water management, water conservation, wetland restoration and management) and a demand for national security for government buildings, landmarks, and monuments.

The Current State of Landscape Architecture

Landscape architecture is faced with the task of design and planning in an increasingly urban world. Two formidable concerns for the future of the discipline are ensuring environmental sustainability from the local to global scales and developing viable, dynamic, and responsive strategies to cope with the changing urban landscape. Also, a promising new movement, landscape urbanism, argues that landscape is the most appropriate organizing principle for the city, one that emerges from the bottom up. It is a hybrid strategy that is inspired by landscape ecology and is thus attentive to the fluid movements of plants, animals, and people, as well as ideas, materials, and time.

LANDSCAPE BIODIVERSITY

Biodiversity, the variety of biological life, is hierarchically organized at different scales, from the molecular and genetic levels to populations, ecosystems, and landscapes. Research on landscape biodiversity studies how the interaction between the distribution of biotic factors and human land use shapes the distribution of biodiversity at landscape scales. Landscape ecology emphasizes the connection between spatial pattern and ecological process. Thus, landscapes are viewed as heterogeneous compositions of many smaller units, typically ecosystems. The type, quality, relative proportion, and spatial distribution of these ecosystems determine the flows of energy, material, and species through the landscape and thus affect the spatial distribution of biodiversity. Abiotic factors such as soils, topography, and climate further interact with and constrain the biological interactions between organisms, resulting in complex spatial patterns of species distribution in a landscape. These spatial patterns in turn influence the distribution of abiotic and biotic resources within the landscape. Thus, landscape biodiversity studies tend to focus on the relationships between pattern (spatial patterns of species distribution) and process (processes of species survival, persistence, growth, and dispersal).

A landscape perspective becomes especially critical for biodiversity management as human impacts on biodiversity increase, since the consequences of human modifications in land use and land cover (such as habitat fragmentation) manifest themselves most severely at the landscape scale yet are often ignored by local ecological

studies. Landscape biodiversity research therefore typically focuses on spatial and temporal scales that are much larger and longer than those addressed in traditional studies of ecology, providing an organizing framework that is useful for land managers and conservation science. For instance, a landscape framework is often used while planning the location of protected areas and parks, such that a park is not created in isolation but is often surrounded by a buffer area of limited human use to improve spatial connectivity and reduce the impacts of habitat fragmentation. Theories of island biogeography, vegetation gradient analysis, and metapopulation dynamics have been influential in landscape biodiversity planning, with conservation biologists striving to protect and restore large, connected landscapes for the survival of rare and endangered species.

Indices of species diversity can be computed at a range of scales, from the local to the landscape level. *Alpha diversity* refers to the diversity of species at a particular location, while *beta diversity* describes the turnover in species between two locations. *Gamma diversity* integrates information from alpha and beta diversity studies to describe the levels of species diversity at larger, landscape scales. The composition and structure of landscapes critically influences gamma diversity, and in-depth understanding of this relationship is critical for biodiversity planning at the landscape scale. The composition of a landscape refers to the number, variety, and relative proportion of the components of a landscape—ecosystems, habitats, and ecological communities. The structure of a landscape is described by the geometry of these components—their size, shape, connectivity, and context—which affects the distribution of specific species to different extents. For instance, area-sensitive species such as large carnivores have requirements for large, unfragmented habitats; edge-sensitive species tend to avoid edges where there are sharp atmospheric gradients and increases in human presence; while dispersal-sensitive species are affected when connectivity between habitats is affected. Thus, other things being equal, patches of greater area constitute better habitat for area-sensitive species. Habitat shape is also critical, as patches of the same size that are more indented or linear have a greater edge, consequently harboring a greater

proportion of edge-generalist species while being avoided by edge-sensitive species. Connectivity between patches affects metapopulation dynamics and determines the overall probability that a species will persist on a landscape. Context is also critical; for instance, an orchard in the midst of a forest is more likely to harbor edge-sensitive forest birds than if it were located in the center of a city.

With the advent of remote sensing and the development of spatial tools for mapping landscapes, hundreds of landscape metrics have been developed that quantify different aspects of landscape spatial structure. Many, if not most, of these metrics are correlated, however, and it is not clear how their increasingly sophisticated computation contributes to biodiversity management. Indices of landscape structure and composition are often treated as substitutes for species diversity assessment. Yet, while simple theoretical models have been developed that relate landscape spatial structure to biodiversity distributions in an intuitively appealing manner, it has been challenging in practice to relate the indices of landscape structure to biodiversity distributions. Thus, the relevance of these metrics for biodiversity planning is unclear.

Several important organizing principles for biodiversity conservation have emerged as a result of using a landscape perspective. Perhaps the best known of these is the often discussed issue of habitat fragmentation, which can pose a serious threat to the movement, growth, reproduction, dispersal, and persistence of species. For example, when old-growth forests are fragmented by the creation of road corridors that cut through them and make it difficult for organisms to move among isolated patches, the survival and persistence of some species become particularly challenging. Awareness of scaling issues is also critical for landscape management, as the lessons learned at one spatial or temporal scale cannot be automatically transferred to another scale. The scale of a landscape is often defined based on human perceptions, and landscapes typically range in size from tens to hundreds of square kilometers. Yet, while this may be the scale most suitable for conservation planning or management, it is also critical to recognize that a landscape can range widely in size when viewed from the perspective of different species—for example,

a tree fungus, for whom a single tree or a clump of trees may provide a landscape, or a large carnivore, which may traverse thousands of kilometers in its lifetime.

LANDSCAPE DESIGN

Landscape design and landscape architecture are in their basic forms a manifestation of humans' passionate care for nature. The two concepts are similar, with landscape design focusing more on the artistic merits of design. This entry briefly reviews the history of landscape architecture and then considers the role that it can play in the future. In an era when we acknowledge the ecological damage and the imbalanced growth that humanity has inflicted on the Earth, landscape design has a significant role to play in the procurement of resources and materials and in the interaction with natural form and elements toward creating livable communities. It also offers solutions for global climate change and warming and peak oil (i.e., the maximum global output that occurred recently and the subsequent gradual decline).

History of Landscape Design

Throughout human history, landscape works such as the Greek and Roman gardens shared a commonality of an incessant love for greenery and plants. Other than these, the “elements” of nature (fire, water, air, and earth in the ancient Occident and metal, water, wood, fire, and earth in the ancient Orient) have influenced the design of ancient gardens. Japanese gardens are designed to provide a natural setting, sometimes referred to as a mindscape, which draws the mind toward meditation. It often reflects the influence of Zen Buddhism and takes a minimal form, sometimes using raked pebbles rather than water.

In the West, the history of landscape architecture can be traced back to Gilbert Laing Meason (1820–1900), a Scot, who was the first to refer to buildings found in the paintings of landscapes as landscape architecture. In the 19th century, J. C. Loudon, A. J. Downing, and others expounded on the development of landscape gardening and contributed to the distinctive style of landscape architecture. Other pioneers included Frederick Law Olmsted (1822–1903), whose works included Central Park in New York and the Emerald Necklace Park system in Boston; Dan Kiley (1912–2004), whose works included Miller Garden in Columbus, Indiana, and the Chicago Botanic Garden; Roberto B. Marx (1909–1994) of Brazil (the Ibirapuera Park and the Flamengo Park); and other landscape masters such as Lawrence Halprin (1916– ; Yerba Buena Gardens Master Plan), Ian McHarg (1920–2001), and Martha Schwartz (1950– ; Dublin Docklands), all of whom were great promoters of landscape architecture in the 20th century.

Twenty-First-Century Challenges

The dawn of the 21st century is marked by four new challenges for the practice of landscape architecture. These challenges arise out of the growing emphasis on sustainability and from the desire to use landscape architecture to enhance the urban experience of life, to explore the therapeutic possibilities of landscape architecture, and to enrich our understanding of cultural landscapes.

First, landscape architects are called on to extend the practice of landscape design to embody

A portion of the rock garden at Kongobuji Temple, located in Koyasan (Mount Koya), Japan

Source: Aliza Schlabach/iStockphoto.

the ecological, social, and economic concerns of sustainability in the planning and design of both indoor and urban spaces. As an example of environmental applications, sustainable landscaping considers a green roof or a roof garden as a rain-water reservoir, a heat sink, and an activity venue, as well as an event for visual enjoyment. Another example is the keen interest that has gone into the research and development of sustainable landscape design strategies and practices, such as artificial wetlands and plant and species selection for enhancing ecological and biodiversity balance in both urban and building settings.

Second, landscape urbanism has appeared, as early as in the past decade, as an extended belief and practice of a contemporary urban theory that holds that landscape, rather than architecture, is an effective tool to enhance urban experience in pursuit of a better quality of life. As a new discipline, landscape urbanism perceives cities as natural processes that are constantly changing and

evolving and therefore demand flexible and adaptable mechanisms in the practice of urban landscape design. This belief is driven by an analysis of the existing and potential conditions of selected sites, which provide a set of parameters for understanding their design as dynamic material organizations shaped by a combination of the temporal and dynamic forces that shape modern cities, from the social and political realms to environmental infrastructure. In this manner, landscape design is integrated with urbanism from a theoretical to a practical sense. This new focus is significant, as it expands the scope for landscape architecture to incorporate urban design. Because of this changing role, many landscape architectural practices have entered the realm of urban design.

Third, human health and performance have emerged as a major stream of “therapeutic” landscape design, often referred to as the Healing Garden School. Roger S. Ulrich in particular has put the spotlight on the ability to deploy designed

natural environments for human health benefits in physical, mental, and spiritual recovery. A successful application of this concept has been the use of “healing gardens” for patient recovery in medical wards; patients have recovered and have been discharged at a faster rate when they were accorded a healing garden. *Therapeutic landscape design* thus refers to a specific aspect of a healing process for the body and the mind. Deeper study of the therapeutic landscape philosophy has led to a growing interest in the extension of the healing concept to the relief of the mind and spiritual relief for identified workers or user groups such as university students working under stressful conditions, inviting a new term, *sustainable campus landscape design*.

Fourth and finally, *cultural landscape* is a new concern initiated by world heritage authorities to promote an awareness of how human activities are intertwined with natural elements. The United Nations Educational, Scientific and Cultural Organization’s (UNESCO) World Heritage Committee (1992) has defined the cultural landscape as encompassing (a) an artificial landscape designed and created intentionally by man or as a result of man working with nature; (b) an organically evolved landscape, including relict landscapes and ones in which the evolutionary process is still in progress; and (c) an associative cultural landscape, because of its association with religious, artistic, or cultural considerations. By this definition, the cultural landscape provides a way to preserve works of landscape, natural or human-made, in order to understand human evolving relationships with nature. An example of a cultural landscape often cited is the Bodie State Historic Park, northeast of Yosemite National Park in California, also known as a gold-mining ghost town, where the terrain landscape preserves the history of the mining activities. In essence, cultural landscape is a collection of places; artifacts that serve as a trigger of memories of social relevance and that are being managed and maintained as a living or a fossil exhibition, such as Pompeii.

LANDSCAPE ECOLOGY

Landscape ecology is a relatively young, interdisciplinary (or transdisciplinary) field drawn from the subjects of ecology, geography, and landscape architecture (see Figure 1). It focuses on the relationships between landscape patterns and ecological processes across a broad range of spatial and temporal scales. Human interactions are strongly emphasized, given the often dominant influence of humanity on landscape composition, structure, and functionality. In the past 20 to 30 years, a variety of pattern indices and modeling techniques have been developed to study the heterogeneous, dynamic, human-modified ecosystems across the globe. Research has cast light on ecological conservation, natural resource management, landscape and urban planning, and sustainable land use in many European, North American, Oceanic, and Asian countries.

Development of Landscape Ecology

The term *landscape ecology* was introduced by Carl Troll in 1939. It was defined as the study of causal relationships between ecological communities and their heterogeneous, patchy environments. The recognition of and emphasis on spatial heterogeneity separated landscape ecology from other classical ecological fields and inspired tremendous research interest in this “spatial ecology.” Other basic concepts of landscape ecology were also formed during this early stage, including scale, hierarchy, and landscape dynamics.

In 1982, the International Association of Landscape Ecology was founded. Landscape ecology, as an emerging academic discipline, began to draw increasing attention from scholars in the fields of ecology, geography, and sociology as well as from designers in landscape architecture and urban planning across the world. The

Figure 1 Landscape ecology

theoretical concepts of landscape ecology evolved rapidly beginning in the 1980s, especially in the exploration of scale and its consequences for pattern and process recognition. Different sets of landscape metrics were created and widely implemented to quantify landscape spatial heterogeneity. Modeling techniques flourished, including neutral models and process-based models. Disturbance and ecosystem succession were extensively investigated and modeled with advanced remote sensing and spatial analysis techniques. Humans and their activities have been increasingly viewed as a landscape component rather than simply an external factor.

Theoretical Approaches

Two landscape ecology approaches are well known; one is the society-centered, holistic view of the European tradition, and the other is the ecology-centered, spatial view of the North American tradition. The former concerns mainly cultural landscapes and focuses on landscape planning that increases the beauty and productivity of urbanized societies, while the latter pays particular attention to natural or human-modified ecosystems and concentrates on the deduction, synthesis, and simulation of landscape pattern-process interactions. Several scholars have advocated that the two distinctive approaches are complementary and, therefore, may be integrated. Others favor the diversity of research methodology and have suggested that while landscape ecology is a transdisciplinary field, individual studies may not have to be cross-disciplinary.

Fundamental Concepts

Despite the differences in the European and North American traditions, the academic disciplines associated with landscape ecology have much in common. Both include the following assumptions:

Spatial heterogeneity is fundamental for the perception of landscape.

The interactions of landscape patterns and ecological processes are the basic subjects of investigation.

Hierarchical views and scaling influence the recognition of landscape patterns and the identification of ecological processes.

Humans are an important landscape component as they modify the landscape and adapt to changes.

Landscape patterns, ecological processes, and human activities are dynamic and intertwining phenomena.

Spatial Heterogeneity

Spatial heterogeneity is the foundation of landscape ecology. It sets the latter apart from traditional ecology, which tends to focus on populations or communities in small and relatively homogeneous areas. *Landscape* is typically viewed as the mosaic of discrete spatial entities at scales ranging from a few hectares to many square kilometers. The patchy appearance of landscape is a reflection of spatial autocorrelation, which is a geographic phenomenon of increasing similarity (or dissimilarity) between locations that are close to one another.

The arrangement (or configuration) of heterogeneous landscape entities is referred to as *pattern*. Patterns may be generated by dissimilar environmental settings, ecological processes, and natural or human disturbances. The perceived pattern of a predefined landscape may vary depending on changes in the criteria for patch segmentation or in the scale of analysis. Tremendous effort has been devoted to the quantification and simulation of landscape spatial patterns since the 1980s.

Pattern-Process Interactions

Understanding the causal relationships between landscape patterns and ecological processes has been a top priority since the establishment of the discipline of landscape ecology. Patterns for landscape are affected by ecological processes, for example, through trophic relationships such as grazing effects on landscape composition and configuration. On the other hand, spatial patterns may influence ecological processes, such as seed dispersal, exotic invasion, and the spread of disturbances. Knowledge of pattern-process interactions has wide implications for ecological

conservation and restoration. However, caution must be taken when investigating and implementing the pattern-process relationships, which might be missing due to the mismatch of sampling scales and the absence of replicate landscapes.

Hierarchy and Scale

The recognition of hierarchy and scale in landscape ecology dates back to the 1950s, and the importance of these concepts has been widely accepted since the 1980s. *Hierarchy* refers to the level of organization, which manifests itself as the nested systems of varying spatial and temporal domains in sequence. For example, a forest landscape may be viewed as a hierarchy of tree gaps, stands, and watersheds from lower to higher levels. Systems at different levels interact with one another, with the lower level generating higher-level patterns and the higher level constraining lower-level processes.

Scale refers to the dimension of space or time for the landscape pattern or process under investigation. From the spatial perspective, scale is viewed as grain (or spatial resolution, i.e., the smallest unit of sampling or observation) and extent (i.e., the size of the study area). From the temporal perspective, scale is regarded as time step (or temporal resolution) and time span, varying from seconds to geological time. Scale is central to landscape ecology, because most landscape patterns and ecological processes are scale dependent, which means that changes in the scale of investigation generate different results for interpreting landscape characteristics.

Hybrid Human-Natural Systems

Today's landscapes are the combined results of historical natural and cultural processes. People's role in shaping landscape patterns and modifying ecosystem functions has become increasingly important, given the advance of society, knowledge, and technology. The impacts of human activities on landscape may be direct or indirect. The former involve modifying the landscape component or configuration directly, as in clearing grasslands for agriculture. The latter occur through manipulation of factors that control the landscape processes, as in the implementation of

fire suppression technology. Both direct and indirect human influences may be regulated and planned to achieve landscape sustainability.

Landscape Dynamics

Patterns of landscape are temporally dynamic and vary with the redistribution of materials, energy, and organisms by natural or human causes. The natural cause of changes in ecological processes may be relatively regular, as in diurnal changes in light availability for plant photosynthesis, or less predictable, as in disturbance events such as forest fires, insect breakouts, and droughts or floods. After a disturbance occurs, ecosystems may restore themselves to their original status through succession without further disturbances. However, because disturbances are often repeated and human modification (such as grazing, logging, and urbanization) is continuous, changes in landscape patterns and processes are often ongoing, never approaching equilibrium, and difficult to predict.

Methodology

Landscape ecology investigates large-extent spatial patterns and ecological processes. One of the most difficult challenges is the lack of replication of landscapes for sampling and experimental design. In contrast with traditional ecology, which is based primarily on experiments, landscape ecology focuses on spatial pattern metrics and simulation models. It also makes use of advanced geographic technologies such as remote sensing and geographic information systems (GIS) for broadscale ecosystem monitoring and spatial data analysis.

Pattern Metrics

Landscape pattern metrics are spatial indices that quantify the landscape composition and spatial configuration of a predefined study area. To apply pattern metrics, the landscape has to be viewed as the integration of discrete spatial units. Each unit is referred to as a *patch*. Patches with similar attributes are assigned to a single class; for example, patches of forested land would belong to the forest class instead of the agriculture or the

Figure 2 Land cover in Leon County, Florida

Source: Data from Florida Fish and Wildlife Conservation Commission. (2003). *Florida vegetation and landcover*. Tallahassee, FL: Author.

residential class. All patches together make up the landscape.

A variety of size, edge, shape, diversity, and contagion metrics have been developed to measure patch-, class-, and landscape-level patterns. *Size* is related to the area of patches. *Edge* describes the characteristics of the patch perimeter versus the patch core area. *Shape* indicates the complexity of a patch compared with a circle or square. All three metrics can be measured at the patch, class, and landscape levels. *Diversity* measures the richness (i.e., the number of patches of a given class) and evenness (i.e., the distribution of area among different classes) of patch classes at the landscape level. *Contagion* refers to the continuity of patches and may be measured at the class and landscape levels.

Landscape pattern metrics are now incorporated in GIS software packages, for example,

Patch Analyst 4 extension for ArcGIS Desktop. It facilitates the analysis of spatial patterns for the landscape where geographic data are readily available through GIS and remote sensing databases. In the following illustration, several commonly used class- and landscape-level pattern metrics were calculated to explore the spatial characteristics of land cover/use in Leon County, Florida. In 2003, seven land cover classes existed in this area (Figure 2), including Urban, Agriculture, Shrub, Forest, Water, Wetland, and Bare, which were aggregated from the original habitat classification of the Florida Fish and Wildlife Conservation Commission. Patches with areas smaller than 1 acre were extracted and merged to the largest surrounding neighbors before deriving the pattern statistics.

Using Patch Analyst for ArcGIS, mean patch size (MPS), edge density (ED), and area-weighted

<i>Level of Analysis</i>	<i>Area (acres)</i>	<i>NumP</i>	<i>MPS (acres)</i>	<i>ED</i>	<i>AWMSI</i>	<i>Diversity</i>	<i>Evenness</i>
Class	Urban	25,427.43	2,359	10.78	34.92	33.37	—
	Agriculture	9,038.34	1,145	7.89	10.53	2.58	—
	Shrub	10,394.10	6,820	1.52	34.32	3.60	—
	Forest	88,977.42	3,541	25.13	96.38	34.18	—

	Bare	11,817.72	3,585	3.30	22.45	5.20	—
Landscape	181,756.98	21,592	8.42	123.07	24.01	1.51	0.78

Table 1 Landscape pattern metrics of land cover in Leon County, Florida

Source: Author.

Notes: Area = class area or total landscape area at the landscape level; NumP = number of patches; MPS = mean patch size; ED = edge density; AWMSI = area-weighted mean shape index; Diversity = Shannon's diversity index; Evenness = Shannon's evenness index.

mean shape index (MSI) were calculated and reported for Leon County at both class and landscape levels, while Shannon's diversity and evenness indices were derived at the landscape level only (Table 1). Results showed that (a) Leon County was dominated by Forest by area; (b) Shrub was the most fragmented land cover type with the lowest MPS, resulting from the highest number of patches and a relatively low number in class area; (c) Forest had the highest MPS among all land cover types, indicating that it was more continuous compared with the rest of the land covers; (d) the shape indices of Forest, Urban, and Wetland were high, indicating the irregular shapes of the three land cover types; and (e) the complicated shape of Forest, Urban, and Wetland contributed to the highest edge density of the three among all the land cover classes. The landscape-level metrics would provide more useful information when comparing two or multiple landscapes or when detecting the temporal changes of a given landscape.

Pattern metrics have been applied widely to the evaluation of landscape heterogeneity as well as to the exploration of relationships between spatial patterns and ecological processes. The results of pattern analysis have practical implementations, for example, wildlife habitat restoration through increasing patch connectivity. However, it is also advised that care be taken when using pattern metrics, which may vary due to inconsistent

criteria for patch segmentation, different solutions in handling edges and borders, shifts in the scale of analysis, and mismatches between landscape patterns and processes. Another limitation of pattern metrics is that they can be applied to discrete data only. For continuous data, geostatistics and graphic approaches provide alternative solutions.

Neutral Model and Process-Based Models

A neutral model is a computer-based simulation technology that produces a two-dimensional (2D) "neutral" map using probability and randomization processes. The term *neutral* is opposite to patterns generated through natural or culture processes. To evaluate whether an observed natural or culture landscape is significantly different from random patterns, neutral models simulate the landscape configuration multiple times (usually 100 to 1,000 realizations) in the absence of certain ecological and/or human factors and compare the overall pattern of simulation results with the observed landscape. Neutral models facilitate the simulation of artificial landscapes, which to some extent compensates for the lack of replication associated with real landscapes.

There are three types of neutral models: (1) complete randomization, (2) randomization with the hierarchical approach, and (3) randomization with the fractal approach (Figure 3).

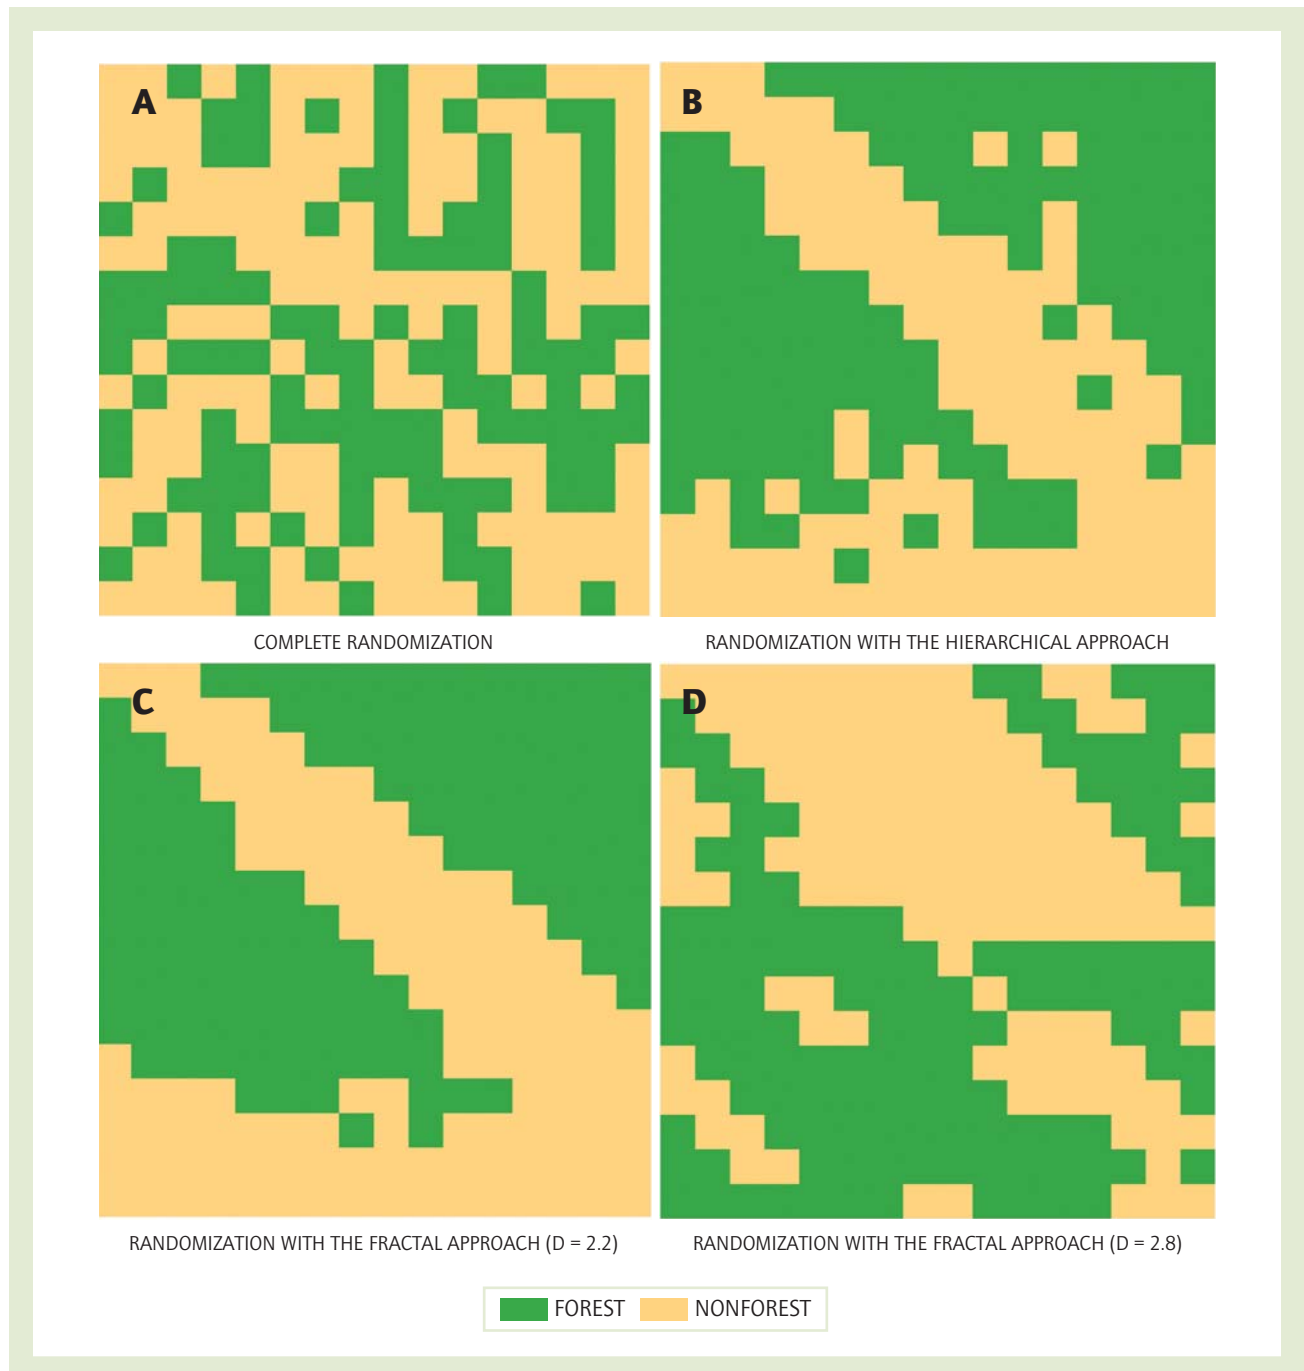

Figure 3 Simulated forest landscapes based on three neutral models. Simulations were performed with the software RULE. Probability of presence of Forest was 0.5 for all simulations. The level of hierarchy was 4 for randomization with the hierarchical approach and randomization with the fractal approach.

Source: Author.

Complete randomization does not consider spatial autocorrelation and determines the presence/absence of a land cover based on probability alone. For example, in a grid of 16 columns $\times$ 16

rows, a random number generator produced a number between 0 and 1 for each of the grid cells. With the assumption that the probability of presence of Forest is equal to 0.5, cells with the

random number ≥ 0.5 were assigned to the Forest land cover type. This resulted in a binary map of Forest versus Nonforest, relatively random in spatial distribution (Figure 3A).

Randomization with the hierarchical approach is simple randomization nested in several aggregation levels. For example, the 16×16 grid may be treated as a hierarchy of four levels, with each quadrature of the higher level divided into four quadrates at the lower level. Assuming that the probability of presence of Forest is equal to 0.75, 1, 0.667, and 1 at each descending level, the total probability of Forest occupancy is approximately 0.5 at the landscape scale (i.e., the product of the four subscale presence probabilities). Simple randomization, the same approach as complete randomization, was performed at each level of hierarchy given the corresponding subscale Forest presence probability. Due to the incorporation of spatial clustering through the nested system, randomization with the hierarchical approach resulted in higher self-organized patterns (Figure 3B) than those produced by complete randomization.

Randomization with the fractal approach is a nested randomization that combines hierarchy and fractal dimension (D). In the 2D space, D measures the resemblance of patches before and after assigning the locations of new pixels with Gaussian randomization. The generated patterns are not correlated when D is 2.5, clustered for lower values (e.g., $D = 2.2$; Figure 3C) and scattered for higher values (e.g., $D = 2.8$; Figure 3D).

In the illustration shown in Figure 3, all four simulated landscapes were produced with RULE, a Microsoft Windows-based software package that generates and analyzes landscape patterns. Probability of the presence of Forest is fixed ($p = 0.5$) for all simulations. The different approaches of neutral models are responsible for the distinctive landscape patterns. The simulated landscape tends to be highly self-organized, with increasing numbers of hierarchy or polarized fractal dimensions.

Process-based models differ from the pattern-based neutral model as they focus more on simulating the mechanisms that drive the changes in landscape patterns and processes. A variety of models have been developed to simulate dispersal, succession, and human behavior. Most of these models are spatially explicit and require the

input of multisource data obtained through ground surveys, remote sensing, and GIS analysis. The process-based models are used to illustrate as well as predict changes in natural and human-dominated landscapes.

Future of Landscape Ecology

Landscape ecology has grown steadily into a well-recognized interdisciplinary field over the past 25 years. Despite the diversity of research topics, landscape ecology developed its own concepts and methods to address the mysteries of the relationships between spatial patterns and ecosystem functions as well as the questions about human-environmental interactions. Understanding the mechanisms of the changing landscape and making reliable predictions of landscape dynamics should be the emphasis of future research. In addition, the rapidly changing global environment and human institutions present new challenges for landscape ecology. Holistic approaches are required to understand the complexity of landscapes. Effective landscape design and sustainable land use are also required to achieve landscape sustainability in practice.

LANDSCAPE INTERPRETATION

Landscape is part of the vernacular of architects, artists, earth scientists, geographers, historians, and planners, although the term has a slightly different use and meaning in each discipline. Geographers, landscape pioneers, initiated the exploration and examination of physical geography, land, and environment to organize knowledge about the world. An early definition of landscape was provided by Alexander von Humboldt, the famous German geographer who viewed landscape 200 years ago as the sum of characteristics that make up a region. The roots of landscape interpretation lie in traditional geomorphology and plant ecology.

The concept of landscape held an important place in the geography lexicon during the two world wars and continues to do so today, although it is now less emphasized. Making meaning to better understand the external environment—whether

on a large scale, such as one's backyard, or a small scale, such as a country or the entire world—is known as *landscape interpretation*. The process includes identifying patterns or structures that change over time and space.

The application of landscape interpretation is far-reaching, having its roots in geography and spanning social and vegetation science, conservation, planning, management, restoration, and landscape appraisal and ecology.

Reading the Landscape

The foundation of landscape interpretation is the skill of simply reading a landscape. Two skills are developed in reading the landscape—seeing with the eyes and thinking about what is seen. Few disciplines, however, encourage students to study the world in this informal fashion. Geography's chorological approach values a holistic examination of particular regions and is a fertile ground for landscape reading.

The process of landscape interpretation examines three general ideas, namely, structure, function, and change. Structure refers to the spatial relationships among distinctive components of the environment, such as energy or resources. Function is the interactions among spatial elements, such as the flows of energy within an ecosystem. Change is the temporal alterations of structure and function.

The American geographer Peirce Lewis developed more specific principles (which he called *axioms* and *corollaries*) for reading the landscape in a systematic way. Among these principles is the observation that landscape is an indication of culture, history, geography, and environmental controls. Human-created structures such as roads and places of worship are evidence that document the imprint of culture, providing explanations of who we were, who we are, and who we will become. For example, in Toronto, Canada, it is not uncommon to see a church juxtaposed with a temple and a synagogue. Such a landscape suggests not only that religion is an important part of the culture but moreover that religious diversity is accepted, with all three religious landmarks equally important in the lives of Torontonians. Peirce also argues that the reading of landscapes, whether contemporary or not, must take into

consideration the historical context in which they were created. For example, a barn that stands in isolation in a field tells the story of a farming community that has since disintegrated in an urban settlement. Another of Peirce's principles is that reading landscapes is tightly tied up with the geography context, as culture and history are location and place specific. For example, shopping malls are not located randomly or throughout a city; rather, they are located in specific parts of the city with transportation and access to a residential catchment area. Peirce also insisted that understanding a landscape is closely related to knowing its physical environment; thus, some basic knowledge of physical landscape is needed. For example, terraces rather than flat farmland are built in some parts of the world where landscapes are too steep for traditional agriculture. Finally, although landscapes convey messages, they do so in a subtle way. As a reader of the surroundings, one should learn to ask questions regarding the appearance and form of the landscape, for example, who designed it, why it was designed, how the structure adds to the story of the location and to the surrounding landscapes, and how the society functions. These questions will unearth information that brings to light the less obvious meanings of landscapes.

Interpretation of the Urban Landscape

Landscape interpretation can occur in several ways, from making personal meaning and developing a sense of place to a systematic, more scientific approach. For most of geography's history, the discipline focused on collecting and organizing facts about physical space. Geographers explored the landscape, measured it, and conducted experiments to study the terrain, by means of geomorphological techniques, surveying, or using topographic maps to examine contours.

The classic work of Kevin Lynch provides a systematic way to understand the mental maps of urban landscapes. Lynch identified five landscape features perceived in all urban spaces: paths, boundaries/edges, districts, nodes, and landmarks. Lynch suggested that the interrelatedness of these elements is important to the formation of place legibility, or the fashion in which people interpret elements and combine them to create

understandable layouts of space. For navigation purposes, the interpretation of a landscape primarily uses paths and landmarks. In people's reproduction of a place, in the form of a mental map or a sketch map, paths are used to frame the boundary and create direction, whereas landmarks are added to give more personal meaning to a location, for example, one's favorite coffee shop or the most frequented gasoline station. Gender differences are often noted in landscape interpretation. In particular, sketch maps by males are frequently dominated by paths (e.g., roads, highways, trails) that are used to indicate direction and the main travel arteries, with relatively few landmarks. Females generally focus on landmarks in their drawings of landscape, often using them to identify neighboring paths.

A major change occurred in the late 20th century, with a shift to understanding the "why," "how," "what," and "where" of landscape. During this time, geography was influenced by different schools of thought, including behavioralism, humanism, Marxism, feminism, postmodernism, the social construction of nature, and postcolonialism. As the field changed, geographers shifted their focus from fieldwork in natural landscapes to the qualitative examination of social relations and land uses, understanding landscapes as complex mixtures of social activities and the natural world.

Interpreting Landscapes With Technology

The quantitative approach to landscape interpretation aims to examine the distribution and abundance of phenomena and processes at a range of spatial and temporal scales. Known as landscape metrics, these quantitative measures distinguish patterns on maps or remotely sensed images. This science is related to landscape interpretation and was termed *landscape ecology* in 1939 by the German geographer Carl Troll, with roots in regional geography and vegetation science. Troll primarily used aerial photographs in his research.

Increasingly sophisticated quantitative measures of landscape patterns have been applied since the late 1980s, whose aim is to correlate the processes occurring in the environment or the ecosystem with the patterns manifested in the landscape, especially those not easily identified by the human

eye. This approach groups measurable variables, namely, shape, size of shapes, and textures, to distinguish patterns in the landscape. These research strategies are of interest to geographers as well as ecologists in examining the patterns of movement of sensitive species to predict whether they may migrate due to fragmentation or increased edges in their current space or whether their habitat size is sufficient for population growth.

Two computerized tools have played a pivotal role in recent landscape interpretation research, namely, remote sensing and geographic information systems (GIS). Remote sensing provides large quantities of environmental data in the form of satellite images of Earth's surface. Such data sets are beneficial for quantitative research for several reasons. First, sensors collect data from a distance, reducing the amount of human bias introduced. Second, data can be collected at different spatial scales, ranging from the local and regional to the national and global, and repeated across temporal scales, such as seasons or years. Third, numerous sensors and spectral ranges are available that specialize and distinguish data collection from specific surfaces such as water, farmland, and urban settlements.

A GIS is a computerized system that stores, manages, displays, and analyzes spatial data. Remotely sensed data in conjunction with related digital information (e.g., the locations of landmarks) can be added to further the analysis. A GIS has several functions. First, landscape features can be visualized or represented in a GIS. The second function of GIS is to predict the consequences of potential changes at different spatial and temporal scales. The third function is to evaluate the impact of the actions taken and to compare the results of alternative solutions.

The quality and effectiveness of landscape interpretation using the outputs of remote sensing and GIS depend on the scale, origin, and reliability (or accuracy) of the input data (e.g., GIS data may be incomplete, remote sensing images may be affected by cloud cover).

LANDSCAPE QUALITY ASSESSMENT

Landscape quality assessment means aesthetic evaluation of an area of Earth's surface. The word *landscape* originates from the 16th-century Dutch word *landschap*, which described paintings of inland natural or rural scenery. Originally translated into English as *landskip*, the term was gradually replaced by *landscape*. Landscape refers to the surface of land and water bodies that may be viewed and includes physical landforms, land cover, and land uses. The adjective *quality* denotes an aesthetic dimension that derives from the human perception of the landscape. The terms *landscape quality* and *scenic quality* are equivalent, *scenery* deriving from stage backdrops but now applied also to the physical environment. *Scenic quality* is the more common terminology in the United States. *Assessment* means some form of evaluation or discrimination of landscape quality. The terms *values*, *preferences*, *amenity*, and *resources* are sometimes substituted for *quality*.

Significance

Combining both their physical origins and the cultural overlay of human presence, and often created over millennia, landscapes reflect the living synthesis of people and place vital to local and national identity. The characteristics and quality of landscapes help define the self-image of a region—its sense of place—differentiating it from other regions. It is the dynamic backdrop to people's lives. Viewing natural landscapes may provide tangible health benefits. Many landscapes attract visitors, thereby supporting tourism and recreational industries and supporting regional economies. Landscape degradation diminishes quality of life. The iconic value of distinctive landscapes is commonly used in advertising. Many World Heritage Areas (as defined under the Convention concerning the Protection of the World Cultural and Natural Heritage, adopted by the United Nations Educational, Scientific and Cultural Organization [UNESCO] in 1972) and national parks are established to safeguard landscapes of outstanding quality. The results of landscape quality assessment may influence relevant policies.

Theoretical Basis

An evolutionary perspective underlies current theories of landscape quality: Preferences for high-quality landscapes are survival enhancing. Far from being casual or trivial, Stephen Kaplan believes, aesthetics are a guide to human behavior and have far-reaching consequences.

Jay Appleton's prospect-refuge theory postulates that, originally, landscapes were preferred that enabled one to see without being seen, that provided places (prospects) where one could spy out game or the enemy while also providing places (refuges) in which to hide. Empirical studies provide some support to this theory while identifying other contributing factors; for example, mountains and trees (prospects) are preferred, but caves (refuges) are not.

Roger Ulrich's affective theory postulates that natural settings and landscapes produce emotional states of well-being in their viewers. When landscape aesthetics are measured on a like-dislike dichotomy, these states correlate closely

with scales such as beautiful-ugly or scenic quality scales. A study of hospital patients found that those with a view of trees recovered more quickly and required fewer analgesics than those without this view.

Gordon Orians's habitat theory postulates a biological imperative for humans to prefer environments likely to afford the necessities of life. He has found strong preference for the African savanna, containing scattered acacia trees amid extensive grassland, believed to be the environment in which humans evolved. The popularity of pastoral landscapes of trees and grass, as found in parks, reinforces his case.

Stephen and Rachel Kaplan apply information-processing theory to landscape aesthetics, arguing that in extracting information from the environment, humans seek to make sense of the environment and be involved in it. They identified four predictor variables: *coherence* and *legibility*, which help one understand the environment, and *complexity* and *mystery*, which encourage its exploration.

A robust theory that provides an all-encompassing framework with which to understand and predict landscape preferences from microlevel to macrolevel, covering all types of landscapes, does not yet exist. A range of theoretical models is available; these offer explanations of aspects of landscape preferences but fall well short of a comprehensive and definitive explanation.

Development of the Science of Measurement

Stimulated in part by legislative mandates, such as the U.S. National Environmental Policy Act of 1970, which required consideration of unquantified environmental amenities by recognition of scenic quality as an environmental resource, scenic quality has been measured by many studies.

These studies lie along a continuum: from physical studies, which measure characteristics directly from the landscape, through preference studies, which measure the human perception of these characteristics in aesthetic terms, to experimental studies, which identify the feelings and experiences of landscape interactions.

Cape Bauer, South Australia

Source: Author.

Physical studies involve the description, analysis, and sometimes quantification of the physical characteristics of the landscape without reference to human perceptions. Forest managers use Visual Resource Management systems (VMS) and, latterly, the Scenery Management System to measure scenic quality from the forest's formal aesthetic features—that is, its form, line, color, texture, and variety. VMS is used to predict and minimize the visual impact of forestry operations.

Preference studies involve people assessing scenes and rating their scenic quality on a scale from low to high (e.g., 1 to 10). Typically, they use photographs of the region being considered and ask people to rate them. Many studies have established the efficacy of photographs as an alternative to field assessment, provided that they are standardized (e.g., color, 50 mm, landscape format, cloud-free conditions, avoiding composition). Separate measures of the components

of the landforms, trees, water, and so on, in the landscape allow, using multiple regression analysis, the development of predictive models of scenic quality based on their features.

Experiential studies examine the aesthetic experiences gained by the community through its interaction with the landscape; these are broader than solely visual and include abstract qualities, evocative responses, and sense of place and meanings. Obtaining consistent results can be a challenge.

Applications

The very act of identifying and measuring scenic quality opens up possibilities not previously available. These include mapping and incorporation into planning policies; defining objectives to manage, protect, and even enhance scenic quality; delineating areas for designation as World

Heritage Areas and national parks or for use in tourism and recreational promotion; selecting routes for roads and power lines; minimizing developmental impacts; and managing forest harvests and forest and fire management.

LANDSCAPE RESTORATION

In the past two decades, landscape restoration has increasingly become a field of research and applied science addressing the multifaceted nature of environmental problems, and it has developed an integrated theoretical framework. Whereas maintenance denotes some regular and relatively slight work directed at conserving a humanized environment, restoration consists of a set of actions designed to improve a degraded or simplified environment. Etymologically, “to restore” derives from the Latin word *restaurare* and from the Old French word *restorer*, which means “to repair,” “to rebuild,” or “to renew.” For environmental purposes, this term implies the memory or knowledge of previous conditions, the negative evaluation of recent alterations and the present context, and the will and means to reestablish an ancient equilibrium.

Many restoration models and practices have been applied to ecosystems. More recently, landscape restoration has broadened its scope, with prospects for the sustainable use and management of natural resources. More than the ecosystem concept, the landscape definition pays particular attention to the human dimension and integrates the actions of and interactions between natural and cultural factors. The landscape perspective does not neglect the negative impacts resulting from the exploitation of natural resources. In addition, it places emphasis on emotional, socio-economic, and cultural elements. It is almost a revolution, insofar as it requires an effort to live today with one eye toward yesterday and the other toward tomorrow, to repair the environment, to recognize the dynamic steady state characterizing the structure and functioning of ecosystems, and to substitute an objective-oriented strategy for a reference-oriented approach.

The meaning of landscape restoration varies according to the scientific community, the type of environment to be restored, and the content of the restoration program. For instance, in Switzerland, the simple repairing of biotopes in a disturbed watercourse is called *revalorization* and attends to biodiversity, spawning areas, or anadromous fish. With *revitalization work*, such as dike shifting or dam removal, the aim is to reestablish the dynamic

processes of water and sedimentation and to widen river corridors for flooding or for prevention of bank erosion. More generally, this distinction underlines the coexistence of structural and dynamical restoration models and highlights the frequent temptation to restore and congeal some idealized forms rather than the processes necessary for their formation and maintenance. It raises the question as to whether such labors may actually effect a restoration. After the restoration of a floodplain lake, how long will it remain connected to the main channel, the water flow, and the bed-load transport, which are disrupted by facilities in the humanized floodplain? Clearly, the continuous stability of a biotope is artificial. The progressive sedimentation of this lake will need some "restoration" work again.

Revalorization is a partial process that aims to make an area more natural, with the objective of "renaturation" being to give an anthropogenic environment its natural features back and to restore its ecological functioning, structure, and equilibrium. In ecological restoration, the original or predisturbance condition is called the "reference state." It is usually characterized through historical investigations. Some restoration actions try to reestablish landscapes. However, in societies that have a long tradition of agricultural and grazing activities, it is not easy to identify and choose a reference landscape. This ethical question opens the debate on different visions of nature in expert or vernacular knowledge. Wild nature often appears as a vanished quest for a "paradise lost." The idea of reversibility, which is inherent in restoration or renaturation work, raises several conceptual, scientific, and technical problems. Moreover, the wilderness often does not respond to social demands. Arcadian nature supplies many valuable landscapes, characterized by attractiveness and aesthetic quality, but tends to achieve and fix an ideal/dream state. Functional nature is densely occupied and is developed to the detriment of naturalness.

Environmental, socioeconomic, and cultural problems are deeply intertwined. Landscape restoration recognizes that nature provides socioeconomic and cultural benefits in the form of goods and services. Public participation is useful to define society's needs and wants, to set priorities in restoration motives, and to select restoration actions.

Rather than a reference-oriented strategy, landscape restoration resorts to an objective-oriented strategy that integrates anthropogenic features and processes. For example, the restoration of hedgerows targets at least three objectives. Ecological studies have shown the value of planted, spontaneous, and remnant hedgerows. More than 500 vascular plant species grow and numerous fauna communities are observed in English hedgerows, which provide them with habitats, prevent them from being attacked by predators, and provide access to food and a corridor for movement of some species. Furthermore, the narrow bands of wooden vegetation modify the microclimate, reduce soil erosion, protect nutrients, and prevent floods in adjacent cultivated fields. Hedgerows also appear as a significant component of traditional rural landscapes, which residents give meaning to through filters of cultural heritage, sense of place, and attractive living space.

Many stakeholders have led landscape restoration programs at different levels, particularly non-governmental organizations (e.g., the World Wildlife Fund and the International Union for Conservation of Nature), federal and national agencies (e.g., the U.S. Environmental Protection Agency and the French Mountain Land Restoration service), and the managers of natural resources. Projects are designed for many environments, such as rivers, wetlands, riparian corridors, woodlands, meadows, hedgerows, and so on. Thus, several partners have selected the landscape level to restore a flooded forest in the north of Mali. While forest restoration considers change a menace—because it causes a loss of diversity, coherence, and identity—and attempts to restore the pristine composition, structure, and functions of the past, forest landscape restoration recognizes the multifunctionality of forested areas and aims at finding an optimal balance of ecological, socioeconomic, cultural, and spiritual interests for trees and forests.

The benefits of landscape restoration derive from a multistakeholders approach, including better governance over natural resources, accommodation of competing land uses, participation of local communities, and collaboration with environmental educators. Therefore, rather than following a preestablished, vain, and rigid model, landscape restoration initiatives integrate the specificities of local territories to elaborate

sustainable and durable projects for environments and societies.

LANDSLIDE

A landslide is defined as the rapid downslope movement of slope-forming materials—rock, soil, debris, or combinations of these materials. In regions of the world where steep slopes combine with heavy-moisture episodes, mass movement and landslides are a risk. Landslides are difficult to predict and prepare for because a wide variety of factors influence the likelihood of a landslide occurring. Landslides are an important geomorphic process in mountainous regions, fundamentally shaping the hydrology, geology, and ecology of a place. This natural phenomenon presents a

significant challenge to people who place property and community in the path of potential landslides, challenging planners, government personnel, and citizens to better understand the complexities of landslide occurrence in their region in order to protect infrastructure, resources, property, and people.

Landslide Classification and Causes

Many systems for classifying mass movements have been created in the past century. The most widely used and accepted classification system in the United States was presented in 1958 by David Varnes in *Landslides and Engineering Practice: Special Report 29*, with revisions in *Landslides: Analysis and Control, Special Report 176* in 1978. Six types of movements are defined in this system, and each type is further divided based on the type of material in which the movement occurs. Slides (landslides) are one of the six types of movements defined (Table 1).

The likelihood of a landslide occurring depends on the relationship between shear stress (forces driving materials downslope, namely, gravity forces) and shear strength (forces resisting the movement of material). More specifically, a slope remains stable if the shear stress exerted on the slope is less than or equal to the shear strength of the slope material (a function of normal stress-resisting movement, cohesion, and the internal angle of friction). When shear stress on a slope is greater than shear strength, mass movement occurs. Factors that either increase shear stress or decrease shear strength, therefore, increase the likelihood of a landslide occurring.

Factors that can increase shear stress include the removal of slope material or the oversteepening of slopes, as can occur with stream erosion or road building; heavy precipitation or snowmelt events that increase pore fluid pressure and reduce resistance to movement; overloading of slopes; and earthquakes. Compositional, textural, and structural properties of rocks and soils and the influence of weathering on these properties are the dominant factors determining the shear strength of a slope. Slope material properties strongly influence cohesion and the normal forces acting on slope material. Cohesion-less slope material, soils with high clay content, and soils

Type of Movement		Type of Material		
		Bedrock	Soil	
			Predominantly Coarse Material	Predominantly Fine Material
Falls		Rock fall	Debris fall	Earth fall
Topples		Rock topple	Debris topple	Earth topple
Slides	Rotational (few units)	Rock slump	Debris slump	Earth slump
	Translational (many units)	Rock block slide	Debris block slide	Earth block slide
		Rock slide	Debris slide	Earth slide
Lateral spreads		Rock spread	Debris spread	Earth spread
Flows		Rock flow	Debris flow	Earth flow
		Deep creep	Soil creep	
Complex	Combination of two or more principal types of movement			

Table 1 Classification of mass movements

Gros Ventre Slide, Grand Teton National Park, Wyoming

Source: U.S. Geological Survey.

The Loma Prieta, California, earthquake on October 17, 1989, near the San Francisco and San Mateo County coast produced this landslide north of Fort Funston. The slide mass is approximately 2,830 m³ of material and is 30 m high.

Source: U.S. Geological Survey.

and rocks composed of inherently weak materials or that become weak with change in water content and jointed rock formations can all decrease the shear strength of slope material, increasing the likelihood of landslide occurrence.

Environmental Consequences of Landslide Occurrence

Landslides are a dominant geomorphic process in mountainous terrains, leaving an unmistakable imprint on the physical geography of mountainous regions at various scales. Deep-seated mega landslides determine the orientation of slopes in some mountainous environments and fundamentally change the organization of fluvial systems. These mega landslides are often closely connected to tectonic events. Common landscape features resulting from surface-based landslides include exposed bare ground at landslide scarps, rounded toe slopes, hummocky topography composed of bumpy mounds and depressions, and abrupt differences in

vegetation on the landslide compared with adjacent stable slopes. Damming of major streams and creation of lakes near the toe of slopes is common with large-scale landslides, such as the Slumgullion earth flow (e.g., Lake San Cristobal) in the San Juan Mountains of Colorado and the 1911 landslide in Tajikistan, which dammed the Murghab River, forming Sarez Lake. Some landslide dams fail soon after formation, while others become long-lasting landscape features. These dams dramatically change sediment/water transport and complementary depositional/erosional cycles in a watershed. Landslides also alter vegetative communities, stripping soil and existing vegetation from slopes to reveal bedrock.

Social Consequences of Landslide Occurrence

According to the U.S. Geological Survey, landslides cause approximately \$1 billion to \$2 billion in damages and more than 25 fatalities on average

annually in the United States. The potential for landslide occurrence must be considered when humans move into mountainous regions, and the danger that people face living in these regions is well documented. On June 23, 1925, a 1-mile-wide section of earth northeast of Jackson, Wyoming, collapsed, damming the Gros Ventre River and creating Lower Slide Lake (see Grand Teton photo). Known as the Gros Ventre Slide, the dam on Lower Slide Lake failed 2 years later, flooding the town of Kelly, Wyoming, and killing six people and hundreds of head of livestock.

Landslide Research in Geography

Research on landslides is extensive. Fields where landslide research abounds include environmental geology, physical geography, geotechnical and civil engineering, hazard management and mitigation, hydrology, and ecology. Primary geographic research themes include landslide recognition and mapping, landslide case studies, analysis of the economic and social impacts of landslides, and predictive model generation for landslide susceptibility using geographic information system (GIS) technology. With rapid development occurring in mountainous regions around the world and numerous examples of human-induced landslides in recent years, the challenge to predict landslide occurrence is immense.

LAND TENURE

Land tenure, or rural property rights, can be defined in several ways. The terms generally concern the ways in which “social relations relate to land use and ownership.” One popular way to view land tenure is as a bundle of rights within a society or community. In such a bundle, rights can be added, removed, or divided to create a very wide variety of rights to land and land-based resources. While land rights are often thought to be produced by titles, deeds, registries, and leases, in reality these are artifacts of a system that involves enforcement, dispute resolution, evidence, identity, forms of logic, institutional formation and operation, and derivation and maintenance of authority and legitimacy. The relevance of land tenure to geography lies in its explicit spatial relevance to Earth’s surface, along with how human elements (based on rights) are arrayed within space. This entry describes the fundamental aspect of tenure security, the types of land tenure, and the more accepted land tenure paradigms.

Tenure Security

Tenure security plays a primary role in the functioning of land tenure. Essentially, it is a “feeling” regarding how secure one is with regard to continued access to and use of one’s land. Such security influences decision making involving investment in and use of lands. Thus, such decisions, along with transactions (buying, selling, renting, loaning, and inheriting), are made based on how secure one’s rights to land are. The logic is that secure tenure leads to making investments (involving time, effort, and money) that are viable over the long term. Thus, there is a connection between tenure security and the rational use and management of resources. Although the concept of land tenure is seemingly straightforward, much research has been undertaken on the nature of tenure security and how it functions, particularly in the developing world, due to the issue’s connections to agricultural productivity and the use of land as collateral for loans. However, tenure security can be difficult to understand, measure, and enhance in a consistent and predictable

way. This is because tenure security is not very tangible, and a wide variety of variables, processes, and contexts are believed to influence it. Generally, secure tenure implies that claims to land are secure because they are defensible against other claims.

A fundamental aspect of tenure security is the means to prove rights to claims by way of evidence. All claims to land are part of a construction of an evidence-based “argument for claim.” Even formal title is only an argument based on evidence that can be, and often is, contested—as are claims based on tribal, ethnic, religious, and other identities. The legitimacy of evidence depends not only on the interpretation or translation of reality into evidence but also on acceptance by others (a community) that the inferences, interpretations, and conclusions are logical and legitimate.

The problem of such proving is at the heart of several popular approaches to land tenure, including the rights recognition approach (recognition of customary or indigenous rights to land), the capital/poverty/property rights approach (described by de Soto and adopted by numerous governments and development agencies), and attachments or claims to land based on identity (with the Palestine-Israel example being perhaps the most extreme).

The “community” aspect of tenure security intersects with how evidence is treated. In many cases, the community is a local village, which has specific internal evidence for a claim that is recognized as legitimate by the community. Evidence at this scale can include community membership, lineage, ethnicity, testimony, land use history, current occupation, and physical signs of occupation. However, such a community can exist within a wider national community in which different evidence is legitimate under formal law. This evidence can value deeds and titles as well as procedures to obtain and defend them. This difference can be problematic because a local community can be unable to defend a claim (using community evidence) against others in a national community (using documentary evidence).

Types of Land Tenure

The primary categories of land tenure types are formal (or statutory) and informal (or

customary). While informal or customary tenure can also be labeled *traditional* or *indigenous*, there are distinctions. Indigenous tenure has to do with particular aboriginal groups and may or may not be customary or traditional. Traditional tenure is largely historical and can have little to do with present-day customary tenure. Thus, customary tenure is a way of approaching tenure that is largely unofficial and comprises the many ways in which people have responded to procedures for institutionalizing land tenure. Customary tenure can be anything from ad hoc to hybridized with statutory tenure and can include traditional or indigenous elements, but it is dynamic and responsive to present-day concerns.

Land Tenure Paradigms

The failure of many past attempts at replacing customary tenure with formal tenure has led many analysts to conclude that there needs to be movement away from the replacement paradigm toward an adaptation paradigm. Such an adaptation approach involves not only the recognition of customary ways by formal law but also the evolutionary transformation of customary law in reaction to exposure to formal law.

While the adaptation paradigm highlights the evolutionary nature of change in both customary and formal tenure systems as these adapt to each other, this approach is different from the evolutionary theory of land rights. This theory holds that population increase results in land scarcity, change in land values, increased uncertainty, and conflict; as a result, a population demands and the state delivers more secure property rights via title. By using population increase and land scarcity as its primary drivers, the theory assumes that the evolution of customary property rights occurs in isolation from interaction with formal tenure systems, which is the central theme of the adaptation paradigm.

LAND TENURE REFORM

Land tenure reform is broadly understood to be a reworking or reorientation of policies, laws, and approaches for managing land tenure—in other words, a restructuring of legal and social relations concerning land. This can include replacing or consolidating laws or making additions to laws to accommodate a new approach to land tenure. Land tenure reform is distinct from land reform in that land is ordinarily not confiscated from some people and redistributed to others as a part of land reform. Thus, land tenure reform is closer to land policy reform. However, land tenure reform can be used to achieve forms of land reform through community-driven land acquisition, market-assisted acquisition, resettlement, or delivery of forms of equity and justice through markets or other incentive mechanisms. The topic is relevant to geography because of the spatial nature of land rights and the ways in which space can be remade or reconstituted with land tenure reform.

Approaches to land tenure reform usually mirror the ideological, social, political, and economic perspectives of those engaged in reform, which may or may not be at odds with those of other sectors of society. Generally, two

approaches to relations about land influence tenure reform. One approach understands land to be a part of the social relations between people, society, and land. More traditional or customary societies favor this approach to land. The other approach pursues the idea that land is a part of the economic relations between people, with land viewed largely as a commodity to be bought and sold—with many types of reform focused on making such transfer easier. Modern industrialized societies favor this second approach. Significant efforts in land tenure reform have sought to move societies from the former to the latter approach. However, the social relations approach cannot easily be legislated out of existence and replaced by market approaches to land. This is because customarily held land also provides important forms of livelihood security and insurance, which are not replaced when land is transformed into a commodity.

Land tenure reform is a priority in many international development agendas, due to its strong relevance in reducing rural poverty and food insecurity. Even so, there is considerable disagreement as to how, when, and for whom such reform should occur. While some advocate the granting of titles to lands, others favor providing greater rights and security of rights to customary forms of tenure. Reform of tenure rules generally assumes that the prevailing approach does not facilitate certain goals, such as poverty reduction, food security, peace, capital mobilization, credit, and so on, and that therefore an improvement is needed. This need for improvement can emerge through change in population pressure, the need for efficiency in landholdings (e.g., family farmers use land more efficiently than large commercial holdings), change in economics, growing land scarcity, land market operation, armed conflict or looming conflict, formalization of customary tenure, and perceived inequity in holdings or the rules under which land is held. While most attempts at land tenure reform are intended to facilitate improvement in peoples' lives, this is not always the case. Some instances of land tenure reform are purposefully political or ethnic, such as the "ethnic cleansing" and the laws that supported this in the Balkans wars in the 1990s.

Many forms of land tenure reform that attempt to improve lives seek to enhance tenure security.

The improvement of such security is thought to facilitate several problems associated with rural property (e.g., food production, credit, land investment), all of which are seen as productive use of land resources. But because the starting point of such reform varies between societies, the reform process and outcomes can vary as well. Reforms that take place with regard to private property, common property, group-held property, property held by particular ethnic groups, scarce land, abundant land, and so on can all take different approaches given the type of improvement needed.

In many cases, land tenure reform is brought to the fore by severe inequity with respect to a number of variables connected to landholdings: location, amount, value, rule-of-law issues, and the viability and legitimacy of dispute resolution mechanisms. This reality is accompanied by the related notion that prevailing, in-place land markets, laws, and enforcement are not able to distribute or redistribute land from the rich to the poor, or vice versa; from unproductive to productive holdings and holders; or from specific groups that are thought to deserve the return or removal of their lands. Because land tenure reform is political, opposition or resistance from some segments of society is normal. Most often, the source of such opposition is those who benefit from the current arrangement and will most likely lose land, wealth, or power as a result of attempts at reform. The obstacles to tenure reform can be strong and take various forms, since the opposition is generally wealthy and connected to or part of the current government structure. However, because the need for such reform can be significant, along with the cost of not reforming, significant political will (often with assistance or pressure from international actors) must often be brought to bear for successful reform to take place.

How to proceed with land tenure reform is a significant concern. While it is easiest to simply import models of land tenure from elsewhere in order to pursue reform, often what works in one society does not work or work as well in another. This is because land tenure is significantly based on history, ideology, and social relations and is not simply a matter of importing law or policy.

LAND USE

Land use is a difficult term to define, as it lacks a standard interdisciplinary definition and is frequently used interchangeably with the term *land cover*. However, these terms have distinct meanings. Land cover refers to the physical and biological cover over the surface of Earth, including water, vegetation, bare soil or rock, and ice. Land use refers to the ways in which Earth's surface has been transformed by human activities such as farming, industry, transport, and urbanization. A close connection obviously exists between land cover and land use, and they are often treated jointly as land use/land cover. The topic of land use is fundamental to the existence of urban planning, is a basic component of many geographical models of urban and transport phenomena, is central to many human-environment interactions, and is an important component of sustainability.

Land Use Regulation

The concept of land use assumes that all land can be surveyed and classified according to its

economic use. Social activities or cultural meanings are generally ignored. The concept is based on applying classifications to land areas and can be used at different scales, such as individually owned parcels of land or larger administrative overlays. It is an inherently spatial concept as it is a statement about what is happening at different locations. This concept provides a basic set of statistics about the allocation of urban and rural space to different activities, which can be measured for jurisdictions at any spatial scale. As there is generally a finite supply of land available in a jurisdiction, an increase in one land use will require a decrease in other land uses. Evaluating changes in land use over time therefore provides a means of measuring economic change in an area.

Land use cannot be discussed separately from the regulation of land uses. In most jurisdictions, land uses are controlled by zoning laws, which govern what activities may be carried out on properties and where different activities may take place. This is based on the notion that certain land uses are incompatible with others, may reduce property values, cause health and safety problems for humans, or result in environmental damage. Land use regulation is therefore aimed at the legal exclusion of particular land uses (such as industry) from certain areas (such as residential areas) to prevent conflicts or for the preservation of environments such as endangered wetlands. This process, in turn, requires classifications based on knowledge of the potential value of different land uses, the effects of land uses on adjacent land uses, and even the effects of the relative abundance of different land uses within a city on land values (or future land values). Implicit in this is the valuation of land uses, whether for increased land value and taxation or for social desirability. However, land use zones do not necessarily specify which land uses actually exist in an area but only what future uses are planned. Land uses existing before a zoning law is created may be allowed to continue. In that sense, zoning represents a preferred or idealized land use classification and map.

Land use policy and regulation in the United States occur primarily at the local level, and they express a community's economic, cultural, and political interests. As a result, land use classifications vary in their details from one place to another. Regulation tends to be greatest in urban

areas. Many rural areas of the United States have very little land use regulation, and sometimes those regulations are designed to protect what in other communities would be considered LULUs (locally unwanted land uses), such as mining and other extraction activities, solid waste landfills, factory farming, and other livestock operations. Since these decisions are made at the local level, neighborhood-based groups sometimes advocate "not in my backyard" (NIMBY) and are often effective at promoting or blocking a land use policy.

Urban land use regulations tend to be use or activity specific, meaning that a number of specific uses are codified and regulated, whereas in rural areas, uses tend to be embedded within a larger conceptualization of use. Many rural land use regulations allow by right (without requiring regulatory approval) uses that support a main use, such as agricultural districts, which typically allow a number of uses that would need special permission in urban areas. Activities that support farming, such as fueling pumps, grain and chemical storage, farmworker housing, and livestock housing would typically be heavy industrial or commercial uses in urban areas, but in rural areas these are ancillary uses to the farm.

Land Use and Geographic Models

Land use is fundamental to several geographic concepts, such as the idea of functional or areal specialization of agriculture, manufacturing, or other economic activities, whether at the metropolitan, regional, or national level. Several models exist to show how land uses may be ordered by distance from one or more points or the conditions under which land uses may be converted to a new use. For example, models of spatial interaction and trade are based on complementarities between places based on their areal specialization in different products and desire to trade these goods. Without areal specialization, there would be no interaction or trade. Land uses are therefore both absolute and relative in location, in that they depend in part on their proximity to other land uses. The phenomenon of space-time convergence has greatly changed the relative location of land uses in developed countries by decreasing travel costs and times and can be expected to trigger transitions to new land uses (as when

farmland is developed for residential land following construction of a new highway) and alter areal specializations. At larger spatial scales, international trade and globalization can affect land uses on the other side of the world. All land uses involved in the global economy are connected, though they continue to be governed at the local level.

Interest in urban land use emerged at a time when different activities or functions began to be conducted outside the home and eventually in different locations within the city. Residential areas became differentiated from industrial workshops and stores, and similar activities began to be found in particular districts or neighborhoods. These spatially distinct homogeneous land uses became fundamental to constructing models of urban space as well as zoning regulations.

The concentric zone model viewed cities as series of concentric zones or rings, with the center zone containing the central business district (CBD) and the social, transportation, and cultural hubs of the city. The model is conceptually a descendant of Johann Heinrich von Thünen's concentric farmland use model based on 19th-century Germany. Both are models in which land use is based on distance from a commercial center. In the Burgess model, various land uses are in competition for space based on their ability to pay for higher valued locations near the center of the city, with the CBD functions having the highest value and therefore occupying the most valuable position. Outside the CBD, the secondary ring was envisioned as a transitional land use area with mixed uses, including manufacturing and low-income or slum housing. Residential density continues to fall as the rings move outward, with residential categories (based on density) and income having an inverse relationship. The poorest residents of the city live nearest the CBD, and the wealthiest reside at the furthest edge of the city. Burgess envisioned an expanding CBD, exerting land use conversion pressure on the surrounding district; this in turn pushed outward on the other districts. In this and later monocentric formulations (and Von Thünen), changes in transport costs determine changes in the relative value, and therefore use, of land at specific distances. More recent polycentric urban models operate much the same but with land use determined by distance from multiple centers.

Land use is also a fundamental component of transportation planning, as standard approaches assume that travel is a derived demand, or a response to a need to carry out an activity at a different location. Certain land uses (such as retail) will attract many trips relative to others (such as landfills). The abundance and location of different land uses is therefore a strong influence on the direction and frequency of travel. Future transport needs of a city cannot be assessed without first forecasting future land uses, and planning the type and location of land uses to minimize the required travel has emerged as a recent objective of many urban planners.

Land Use Classifications

Land use classification in the United States is based on hierarchical and segregated uses. This implies that land uses exist as (or can be divided into) discrete, nonoverlapping categories and that there exist a few basic types of land use that can be subdivided to provide more detail. These types can then be quantified and mapped. There are several different approaches to land use classification, but the most commonly used are the Anderson land use classification scheme and the Land-Based Classification Standard (LBCS) system.

Anderson Land Use Classification Scheme

For many years, U.S. government agencies collected data about land use, but there was a lack of coordination and uniformity in their classification schemes. As a result, it was impossible to aggregate existing data to make a comparison between land use changes from time to time or place to place. In 1971, James Anderson (with others) worked with the U.S. Geological Survey, National Aeronautics and Space Administration, U.S. Department of Agriculture, Association of American Geographers, and International Geographical Union to develop a national classification system for land usage similar to the economic classification codes applied to commercial and industrial activities. Anderson's classification scheme drew heavily on a system developed for the state of New York but gave special attention

First Level Code (1–9)	Level II	First Level Code (1–9)	Level II
1 Urban or built-up land	11 Residential 12 Commercial and services 13 Industrial 14 Transportation, communications, and utilities 15 Industrial and commercial complexes 16 Mixed urban or built-up land 17 Other urban or built-up land	5 Water	51 Streams and canals 52 Lakes 53 Reservoirs 54 Bays and estuaries
2 Agricultural land	21 Cropland and pasture 22 Orchards, groves, vineyards, nurseries, and ornamental horticultural areas 23 Confined feeding operations 24 Other agricultural land	6 Wetland	61 Forested wetland 62 Nonforested wetland
3 Rangeland	31 Herbaceous rangeland 32 Shrub and brush rangeland 33 Mixed rangeland	7 Barren land	71 Dry salt flats 72 Beaches 73 Sandy areas other than beaches 74 Bare exposed rock 75 Strip mines, quarries, and gravel pits 76 Transitional areas 77 Mixed barren land
4 Forest land	41 Deciduous forest land 42 Evergreen forest land 43 Mixed forest land	8 Tundra	81 Shrub and brush tundra 82 Herbaceous tundra 83 Bare-ground tundra 84 Wet tundra 85 Mixed tundra

Table 1 Anderson's land use classification scheme

Source: Anderson, J. R., Hardy, E. E., Road, J. T., & Witmer, R. E. (1976). *A land use and land cover classification system for use with remote sensing data* (Geological Survey Professional Paper 964). Retrieved December 12, 2008, from <http://landcover.usgs.gov/pdf/anderson.pdf>.

to the definition of land use categories used by other federal agencies so that homogeneity and compatibility could be preserved from the past. The system was specifically designed for use with remote sensing applications, which were becoming increasingly common at the time.

Anderson's land use classification scheme is a hierarchical system with coding by digits, in which the first digit designates the broadest descriptor and ensuing numbers provide a sharper focus (Table 1). For instance, first digits show the major category (e.g., 1 = urban or built-up land, 2 = agricultural), while the second digit shows sub-division (e.g., 11 = residential, 12 = commercial

and services). The system was designed so that land uses could also have a third digit if necessary for a land use inventory at more detailed levels (e.g., 111 is for single-family home units, 112 is for multifamily units).

In Anderson's classification, *urban and built-up land* refers to areas of intense human use with a high density of built structures such as cities, towns, villages, and strip developments along highways. This land can be further subdivided into categories such as commercial, residential, industrial, transportation, communication, and utilities and also mixed land (in situations where no single dominant land use can be distinguished).

Agricultural lands uses are those areas that are used primarily for the production of food and fiber, including wetlands when they are drained for agriculture purposes. *Rangeland* is those areas where vegetation such as grasses and shrubs used for grazing animals are found. *Forest land* consists of areas where a closed tree canopy makes up at least 10% or more of the area or areas that are stocked with trees capable of producing timber or other wood products. *Water* includes all those areas within the landmass that are persistently covered with water; these must be at least one eighth of a mile wide if linear or at least 40 acres if extended. *Wetland* includes areas dominated by woody vegetation such as mangrove swamps, shrub swamps, and so on, as well as nonforested wetlands. *Barren land* is land that has limited ability to support life, where less than one third of the area has vegetation cover (e.g., areas of thin soil, sand, or rocks). *Tundra* areas are characterized by extremely cold climate, a variety of vegetation, but low biotic diversity. Finally, the *perennial snow* or *ice* category comprises those areas where this feature is permanent.

Land-Based Classification Standard System

A new LBCS was developed by the American Planning Association in 1994. The purpose of the LBCS system is to support planning applications at different geographical scales. It is an attempt to synthesize land use according to five parameters: human activities, functions, building types, site development character, and land ownership. These multiple dimensions allow users to have precise control over land use classifications, and each dimension can be defined at different levels of detail. The *human activities* dimension of classification directly describes human use of land and is shown in Table 2. These classifications are subdividable into secondary and tertiary categories, such as shopping (2100) and goods-oriented shopping (2110).

An economic function of land or types of establishments on land makes up the functional dimension and is shown in Table 3. Function classifications have a fourth subcategory of ownership, which provides an added layer of detail to the classification. The structure parameter delineates the type of building or structure on the land,

Code	Description
1000	Residential
2000	Shopping, business or trade
2100	Shopping
2110	Goods-oriented shopping
2120	Service-oriented shopping
3000	Industrial, manufacturing, and waste-related
4000	Social, institutional, or infrastructure-related
5000	Travel or movement
6000	Mass assembly of people
7000	Leisure
8000	Natural resources-related
9000	No human activity or unclassifiable activity

Table 2 LBCS—human activities parameter

as shown in Table 4. The site-based parameter indicates the current physical state of the land (Is it developed? Developing? etc.), as shown in Table 5. The final LBCS parameter is ownership of the land, which is shown in Table 6.

Despite their detail, these land use classifications have some limitations. For instance, they do not allow for vertical zonation of land uses (such as below- and aboveground or on different floors of a building) or changing land uses at different times of the day, week, or year. In some cases, vegetation is used as a surrogate for human activities. However, even rural land may be used for a specific purpose without any change to the vegetation or the presence of human artifacts, for example, wilderness or parklands. While the LBCS resolves many land use nuances that the Anderson scheme cannot identify, no single scheme can be expected to work for all applications or in all areas.

Code	Description
1000	Residential buildings
1100	Single family building
1110	Detached units
1120	Attached units
1121	Duplex structures
1122	Zero lot line, row houses, etc.
1130	Accessory units
1140	Townhouses
1150	Manufactured housing
1200	Multifamily structures
1300	Other specialized residential structures
2000	Commercial buildings and other specialized structures
3000	Public assembly structures
4000	Institutional or community facilities
5000	Transportation-related facilities
6000	Utility and other non-building structures
7000	Specialized military structures
8000	Sheds, farm buildings, or agricultural facilities
9000	No structure

Table 4 LBCS—structure parameter

Land Use and GIS

The innovation of geographic information systems (GIS) technology allows the integration of various sources of land use data such as original land (field) surveys, aerial photographs, satellite imagery data, land use and land cover maps, forest inventories, and property records (to reconstruct ownership history). In this way, GIS technology has become an important means of advancing the understanding of the spatial, temporal, and decision-making apparatus of land use and land use changes over the past two decades.

There are a wide variety of GIS data sets for land use. In the United States, at the local level, there are parcel and zoning data sets created by individual cities and counties. Land parcel data (also known as *cadastral* data) represent the smallest geographic level, which describes the rights, interests, ownership, value, and use of land. Because these data are created by individual county assessors, their cost and availability vary from one county to the next. Most local governments create digital versions of their local zoning/land use regulation maps at a scale of 1:4,800. Similarly, zoning data, which reflect legislative regulations through which a city or county government seeks to control the use of buildings and land within its jurisdiction, may be available through local planning organizations.

In addition, two national land use data sets are available for the United States: Land Use and Land Cover (LULC) and National Land Cover Database (NLCD). Manual interpretation of aerial photography (land use maps and surveys) over two decades resulted in the vector LULC database in the 1980s. Areas of discrete land use are mapped using individual polygons, with 37 land use/cover categories. Most of the country is covered at a scale of 1:250,000. However, there are some gaps: For example, only the area around Valdez is available for Alaska. At a scale of 1:100,000, the coverage is even more limited.

NLCD is a raster data set based on LANDSAT satellite images developed in the 1990s by a consortium of federal government agencies. Several versions have been released: The first one was in 1992 (NLCD92), with 21 classes, and covers the coterminous United States, while NLCD01 has 2001 data and covers the entire United States;

and a 2006 version is under preparation. Land uses are mapped at 30 meters' resolution. Both LULC and NLCD data sets use a similar, although not identical, land use classification scheme based on Anderson. Because of their different classification and formats, LULC and NLCD are not directly compatible.

LAND USE ANALYSIS

Land use analysis is the quantitative and qualitative assessment of how humans use land. It addresses three types of questions concerning the what, why, and how of land use.

What Is Land Use?

The first step in land use analysis is to map the land covers and land uses of a study area. There is an important distinction between land cover and land use.

Land cover is the physical cover of the land. For example, two common types of land cover are *built* and *forest*. Land cover can be observed and documented via remote sensing using sensors that are mounted on satellites, airplanes, or ground-based platforms. Cartographic methods are necessary to convert the information from the sensors into maps of land cover categories. Maps of land cover indicate what is on the landscape physically.

Land use is the purpose for which humans use the land. For example, common land uses are *residential* and *recreational*. Remote sensing techniques usually do not reveal land use because they give information about only the physical state of the land. A single land cover type may have many uses. For example, humans can use the forest land cover simultaneously for tourism, biodiversity conservation, and water quality protection. It is usually necessary to collect social data to determine land use, because land use is a social phenomenon.

Scientists are constantly developing more sophisticated methods to generate maps of land cover and to record the various land uses for each land cover. When maps of land use are available from more than one point in time, investigators usually want to characterize land use and land cover change. If the land uses are categories, then a transition matrix is commonly used to summarize the land transitions among the categories over time.

Why Do Humans Use the Land the Way They Do?

The second step in land use analysis is to understand why humans choose some land uses over

other possible uses. The philosophical orientation of the investigator can influence the approach taken to attain this understanding. For example, an economist is likely to examine land prices and financial subsidies in an attempt to understand why developers prefer some locations over others for suburbanization. Sociologists may consider family dynamics and customs to understand how settlers decide to colonize a forest in a manner that maximizes land for future generations. Geologists might examine the soil fertility to explain the spatial distribution of farms. Regardless of the orientation of the investigator, analysts usually find it helpful to use both quantitative and qualitative techniques. Quantitative techniques include statistical methods to examine the association between the patterns in the land use maps and other variables such as prices, family structure, and soil fertility. Qualitative techniques include interviews with stakeholders and historical research concerning the policies that have guided land use decisions.

Land use analysis faces daunting methodological and conceptual challenges. Statistical analysis is complicated by the fact that the results can be sensitive to many characteristics of scale. These characteristics include the spatial, temporal, and categorical scales of the data in terms of both extent and resolution. Furthermore, the data are usually observational, that is, the data are not obtained from controlled experiments, and so large statistical associations do not necessarily guarantee cause-and-effect relationships. Qualitative analysis faces the same challenges. Some of these challenges derive from the fact that the land use system is a complex web of many interacting decision makers who are constantly responding to a variety of types of dynamic information. A major challenge for land use analysts is to be able to state clearly the evidence for a particular hypothesis for a particular domain at a particular scale and not get lost in the complexity. Some scientists use modeling to help gain an understanding of the land system. A land-change model is a computerized algorithm that shows the implications of the many assumptions that it synthesizes. It usually includes a calibration procedure during which it examines the past dynamics of the land use system. Then it can project future land uses based on either an extrapolation of past trends or alternative assumptions.

How Should Humans Manage Land?

The third step in land use analysis is to apply the understanding gained in the previous two steps to offer guidance on how humans should use land in the future, given particular objectives. Typically, this is done through participatory exercises that involve a variety of stakeholders at the level of the village, town, state, nation, or globe. Land use analysts can facilitate discussions among stakeholders by offering scenarios of future land uses. A land use scenario is a story told in words, numbers, and maps concerning the manner in which humans could manage land, including the consequences of those management decisions. Scenario analysis can examine the implications of a scenario that assumes a continuation of present land management practices and can contrast the results with alternative scenarios that might lead to a more desirable future. Such scenarios can help stakeholders envision possible futures and relate those futures to management decisions.

LAND USE AND COVER CHANGE (LUCC)

Land use and cover change (LUCC) refers to the alteration of Earth's terrestrial surface. The terms *land use* and *land cover* may seem to be interchangeable, but they are not equivalent. Land cover denotes the observed biological and physical attributes of Earth's terrestrial surface, such as vegetation, water, earth materials, and human-made features. Land use signifies the purposes to which the varied resources offered by the biophysical attributes of land cover are exploited by human activities, such as cropping, logging, and building construction. Forest, for example, is a land cover type that may be exploited for land uses as diverse as cultivation, recreation, and settlement.

Studies of land cover and land use were historically separate; the former was largely studied by natural scientists, the latter mainly by social scientists. Connecting the two components are proximate sources of change in human activities that directly modify the physical environment. A change in either land use or land cover is not essentially the product of the other. Changes in land cover may not directly cause land use change, but with further environmental consequences, they may ultimately affect land use. Conversely, changes in land use are likely to result in some land cover change, but other forces such as climatic fluctuations and ecosystem dynamics can also drive land cover change. This entry reviews the history of research on LUCC and describes some of the most important consequences of LUCC, including its impact on biogeochemical cycles, the hydrologic cycle, biodiversity, and human health. It then examines issues related to monitoring, measuring, and modeling LUCC.

Development of LUCC Research

Concerns over the effects of human activities on the environment may be traced back to when George Perkins Marsh published his book *Man and Nature* in 1864. The consequences of LUCC, such as deforestation leading to soil erosion and

Figure 1 The number of published papers between 1980 and 2007 with land use and/or land cover as their subject

Source: Created by author using data from ISI Web of Science.

subsequently decreased soil productivity, were debated on. LUCC has in the past several decades emerged in the global environmental change research agenda. In the 1970s, it was recognized that land cover change modifies surface albedo and, thus, surface-atmosphere energy exchanges, influencing regional climate. In the early 1980s, terrestrial ecosystems as sources and sinks of carbon were highlighted, underscoring LUCC as a major element of the global carbon cycle. Studies focused on LUCC came into the limelight in the mid 1990s. This can be seen in the growing

number of publications on this topic in the past decade (Figure 1). The need to have a framework for LUCC studies at a global scale, to integrate the social and natural sciences, and to provide greater data availability and standardization also spurred the development of various national and international research programs. In 1994, a core project on LUCC was initiated and jointly run by the International Geosphere-Biosphere Programme (IGBP) and the International Human Dimensions Programme (IHDP) on Global Environmental Change. The International Geographical Union

(IGU) established a study group on land use and land cover in 1996 to promote LUCC studies in the world geographical community. In the United States, the National Aeronautics and Space Administration developed a Land Cover and Land Use Change research program, synthesizing the results from different regions where important LUCC processes are taking place, such as the Brazilian Amazon, China, and southeast Asia. These programs and many others worldwide have made considerable progress and demonstrated the importance of cross-disciplinary efforts in addressing the LUCC issues. Because of its stand-alone significance and its critical role in other aspects of global change, LUCC research continues to gain programmatic support.

Consequences

Most of the current LUCC is caused by anthropogenic processes such as urban expansion, a direct cause of land use change, and alteration of fire regimes, an indirect cause leading to land cover change. Anthropogenically induced LUCC affects Earth's systems with many interrelated consequences.

Biogeochemical Cycles

LUCC has significantly influenced the cycling of essential nutrient elements, such as carbon, nitrogen, sulfur, and phosphorus. Extensive clearing and burning of natural vegetation and conversion of forests to agriculture have released carbon into the atmosphere, which may contribute to global warming. In past centuries, modifications generally took place in the temperate grasslands and forests; in the past several decades, forests in the tropics have encountered greater transformation. The high biomass levels of tropical forests comprise a substantial portion of carbon storage; the impact of tropical deforestation on global carbon cycling will thus likely be significant. Intensification of agricultural land use has also profoundly influenced nitrogen and phosphorus cycles. For example, high use of nitrogen fertilizers results in the leakage of soluble nitrate from agricultural systems, causing soil acidification, groundwater pollution, and eutrophication of streams and lakes.

Hydrologic Cycle

Changes in land cover, particularly the removal of forests and the growth of impervious surfaces during urbanization, significantly influence hydrological processes, causing increases in runoff, flooding, soil erosion, and sedimentation (see photo). The hydrologic cycle is the matrix in which all other biogeochemical cycles function. The interactions among LUCC, hydrologic cycling, and biogeochemical cycling may consequently increase the frequency and magnitude of extreme weather events, with the potential to drastically affect ecosystems through changes in temperature and precipitation. The combination of LUCC and climate change may have profound effects on Earth's systems in more significant ways than either acting alone.

Biodiversity

Habitat loss is probably the greatest threat of LUCC to biodiversity. It occurs through habitat fragmentation, such as road construction and deforestation, or habitat conversion from, for example, undisturbed forest or grassland to (eventually) urbanized land. Besides, LUCC often accompanies species introduction, decreasing the diversity of native species. Because biodiversity provides ecosystem goods for basic human needs, from food and fiber to medicines, and ecosystem services such as water purification, crop pollination, climate regulation, and aesthetic beauty, a major loss of biodiversity affects ecosystem functioning, threatening the capacity of Earth to support human societies.

Human Health

LUCC in conjunction with climate change has the potential to facilitate the spread of pathogens and parasites, rendering human societies vulnerable to disease. Vector-borne infectious diseases, such as malaria in Africa and India, liver fluke in southeast Asia, and Lyme disease in the United States, are particularly sensitive to LUCC because LUCC influences the availability of suitable habitats and hence the abundance of the vector and may facilitate the migration of vectors capable of transmitting diseases into previously uninhabitable areas. For example, the spread of irrigation

Sabah, Malaysia, February 2007. LUCC such as deforestation influences hydrologic cycling, causing high sedimentation in rivers.

Source: Author.

systems associated with agricultural intensification alters the temperature and moisture of an area, which in turn can trigger dramatic increases in vector populations and transmission rates for malaria. It is important to understand that socioeconomic factors influencing land use patterns also play a role in disease transmission. The changing location of human settlements in relation to vector habitats modifies the exposure of people to contacts with the vector. As a result, investigation of the consequences of LUCC requires an interdisciplinary approach integrating both natural and social scientific methods.

Monitoring, Measuring, and Modeling of LUCC

Studying LUCC and its causes and consequences frequently requires monitoring LUCC, measuring how much change has occurred, and modeling

the dynamic processes of LUCC under different scenarios.

Monitoring

Remote sensing data offer an important source of information for spatially explicit monitoring of LUCC. Aerial photography is one of the most common and economical forms. It came into widespread use in the late 1930s and has been used to prepare land use maps in many countries. Aerial photography allows long-term and detailed monitoring of LUCC because of its routine acquisition over multiple decades by many government agencies.

Alternatively, satellite imagery has the advantage that a single image covers an extensive area. The deployment of satellites for monitoring Earth's surface resources since 1972 has provided continuous land use/cover data layers for global

land cover inventories. In some regions, satellite imagery is the only practical way to provide timely and reliable assessment of land cover and identification of rapid LUCC. The extensive spatial coverage and frequent temporal intervals that satellite imagery provides would be difficult to obtain from in situ field surveys. However, since satellite imagery relies on spectral reflectance, incorporating ground-based data into analysis of satellite imagery is essential to improve the quality of land use/cover data.

Satellite images are now available at high, medium, and low spatial resolutions for monitoring LUCC at various scales. The Moderate Resolution Imaging Spectroradiometer (MODIS) provides daily global observations of land cover at 250-m (meters) spatial resolution and is often used to characterize land cover and its changes at the global and regional scales. Hyperspatial data with 1- to 4-m resolution from sensors such as IKONOS and Quickbird are available for detailed monitoring of LUCC at the local scale.

Measuring

The conventional way to detect and measure LUCC is to visually compare a series of land use/cover maps of different snapshots derived from remote sensing data or other sources of information of the same area, but such a comparison may disallow the quantification of subtle changes. Change detection is another common approach for measuring LUCC. Unlike statistical summaries that provide data on land use/cover types of different years in areas or percentages, change detection compares land use/cover databases from two different time periods to determine the location, spatial extent, and nature of changes over time. Transition matrices are used to show changes in land use/cover types from one time period to another; the changes in land use/cover from one category to another can then be illustrated in maps. This approach offers more quantitative insights into LUCC. Care must, however, be taken to ensure that the differences between dates are not due to artifacts of the source data.

The development and diversity, in recent decades, of new technologies and methods used to create land use/cover databases suggest that there may be great disparities in the quality and

organization of data. Additionally, data may not be collected according to categories and definitions consistently enough to make different sets comparable. Measuring and quantifying LUCC thus require more standardized classification systems that can be applied uniformly over the time series of analysis.

Modeling

LUCC modeling, such as predicting future LUCC and simulating possible LUCC consequences on human and natural systems, provides insights that can be used to assist policymakers and land managers in sustainable resource management. Models are required because they help enhance our understanding of the dynamic patterns and processes of LUCC that result from the complex interactions among physical, biological, and socioeconomic forces. Advances in geospatial techniques and computational methodologies have improved the capacity needed to model LUCC at different spatial and temporal scales in relation to various human activities. Although land use/cover patterns may be obtained from remote sensing data, modeling the dynamic processes of LUCC requires incorporation of the historical and contemporary causes of the changes. A combination of various biophysical and social data in modeling, such as interviews with land managers, population data, household surveys, land use/cover history, soil maps, and ecological measurements, is thus needed.

Various land use/cover models are available for explanatory or predictive purposes. The combination of agent-based models, used to describe human decision making, with cellular automata models, used to represent biophysical landscape change, offers a promising approach for future model development in LUCC.

LAND USE AND LAND COVER MAPPING

Land cover refers to the observed physical layer of Earth's surface. It includes vegetation and anthropogenic features as well as bare rock, bare soil, and inland water surfaces. Reliable land cover mapping is of crucial importance for (a) understanding and mitigating climate change and its impacts, (b) sustainable development, (c) natural resource management, (d) biodiversity conservation, and (e) understanding of ecosystems and biogeochemical cycling. For example, land cover characteristics reveal ongoing processes of deforestation, desertification, urbanization, land degradation, loss of biodiversity and ecosystem functions, and water and energy management. In situ and satellite-based land observation efforts as well as different disciplines (e.g., geography, ecology, geology, forestry, land policy, and planning)

use and refer to land cover as one of the most obvious and detectable indicators of land surface characteristics and the associated human-induced or naturally occurring processes.

The Process of Land Use and Land Cover Mapping

The primary units for characterizing land cover are categories (e.g., forest or open water) or continuous variables classifiers (e.g., fraction of tree canopy cover). Secondary outputs of land cover characterization include the surface area of land cover types (in hectares), land cover change (area and change trajectories), and observation byproducts such as field survey data or processed satellite imagery. In applications using land cover maps, the original land cover categories are often associated with specific attributes (e.g., average carbon stocks, degree of artificiality, or function in the hydrological system). In current practice, many national and regional observation programs and research institutes still do not distinguish between land cover and land use. Land use characterizes the arrangements, activities, and inputs people have undertaken on a certain land cover type to produce, change, or maintain it. Observation strategies and methods vary for observing land cover, land use, and associated changes. Common and operational procedures exist for observation of land cover; observing land cover change, land use, and land use change is more challenging and still a subject of research.

Land cover and land use mapping activities can be understood as a process of information extraction governed by the rules of generalization. The degree of generalization, and thus the efficiency of representing reality in a two-dimensional form, is linked to three major factors: (1) the “thematic” component refers to the land classification system and the adopted land cover legend; (2) “cartographic” standards include the spatial reference system, the minimum mapping unit (MMU), and the mapping scale; and (3) the “interpretation” process reflects the characteristics of the source data, the interpretation procedures, and the skill of their use. These factors affect the map products—their content, quality, flexibility, and efficiency for specific applications.

Applications of Land Use and Land Cover Mapping

Land cover and land use in different regions have been mapped and characterized at various times, and many countries have implemented some kind of land monitoring system (e.g., forest, agriculture, and cartographic information systems and inventories). In addition, there are many continental and global land cover map products and activities. There is, for example, a quasi-operational global land cover monitoring system, which integrates information from three common observational scales: (1) moderate-resolution satellite data (e.g., MODIS- or MERIS-type satellite sensor), (2) fine-resolution satellite data (from Landsat- and SPOT-type satellite sensors), and (3) in situ observations (or very high-resolution remote sensing data). Continuity of observations and consistency of land cover characterization is required for all these scales.

Extensive information on land cover has been produced in many regions of the world. The varying purposes, data sources, accuracies, spatial resolutions, and thematic legends of these efforts have resulted in a suite of more or less

incompatible land cover data sets. Many of the available global, regional, and national mapping products exist as independent data sets. For example, multiple definitions and thresholds for a particular land cover type, such as forests, result in different representations of forest class in the different land cover maps. The lack of consistency has triggered the need for harmonization and standardized land cover monitoring. Land categories and classifiers must be defined consistently to identify land cover changes over time. The United Nations (UN) Land Cover Classification System (LCCS) classifiers and the related Land Cover Macro Language provide a comprehensive and flexible framework for thematic land cover characterization. LCCS classifiers enable compatibility to be achieved between existing data sets and for future monitoring of data. An independent accuracy assessment using a sample of ground or other reference data is an integral part of any land cover and land use monitoring effort.

There is a need for both maps (static and updated) and dynamic land monitoring products at different spatial and temporal scales as part of an integrated global land monitoring system (Table 1). These outputs require different sets of

<i>Name</i>	<i>Spatial Resolution</i>	<i>Frequency of Product Update</i>	<i>Maturity</i>
Mapping of land cover			
Land cover maps	250 m–1 km	Annual	Preoperational
Fine-scale land cover and land use maps	10–30 m	3–5 yrs.	Preoperational (for land cover)
Global land cover reference sample database	In situ/1 m	1–5 yrs.	Preoperational (CEOS, GOFC-GOLD)
Monitoring of dynamics and change			
Global land cover dynamics and disturbances	250 m–1 km	Intra-annual/long-time series	Preoperational (for several processes)
Fine-scale land cover and land use change	10–30 m	1–5 yrs.	Preoperational (for land cover)
Monitoring areas of “rapid change”	1–30 m	1–2 yrs. or less	Preoperational (for some change processes)

Table 1 Characteristics of land cover and land use mapping and monitoring products that are useful for observing land cover as an essential climate variable

observations and monitoring approaches. There is also a need to ensure synergy with other observation products (e.g., fire, biophysical parameters, snow cover) that are directly related to land cover and land use characteristics.

Ongoing global mapping efforts (i.e., MERIS-based GLOBCOVER and those using MODIS data) provide consistent and validated land cover data and land cover change indicators worldwide at moderate spatial resolution (250-meter to 1-kilometer spatial resolutions). Land cover and land use change estimates require multitemporal fine-resolution satellite observations. Archived image data (e.g., global Landsat data) and methods are available to implement a global land cover change monitoring system. Global assessments of historical forest change processes based on multiple data sources are available from regional and national programs (e.g., the European CORINE, Brazilian PRODES) and international initiatives, such as the Forest Resources Assessment of the Food and Agriculture Organization of the United Nations.

LAND USE HISTORY

Land use history—the story of human use of Earth's surface and its resources—reflects the record of anthropogenic manipulation of the natural environment. In preagricultural times, this impact was largely confined to fires. The first major land use changes took place with the transition from hunting and gathering communities to agricultural societies. Further changes can be associated with the adoption of new farming techniques and crops as well as with social and historical developments. Starting with the Industrial Revolution in the 19th century, however, land use has become one of the dominating forcing factors of environmental change, gradually affecting natural ecosystems on a global scale. Land use interferes with the climate system as well as with biogeochemical and hydrological cycles and has become a major topic in the context of global change. It has been related to many environmental problems, such as climate change, desertification and soil erosion, biodiversity loss, and emission of greenhouse gases. Thus, knowledge of land use history is crucial to evaluate the impact and consequences of past land use practices on the environment and to use this information to project future developments.

Research Topics and Methods

Land use practices are essential to sustain human life and are determined by environmental settings of the landscape (e.g., climate, soil type), social and cultural conditions, and human needs and skills (e.g., farming techniques). Land use history therefore reflects both environmental and human development and their interactions through time. Studies of historical land use changes are helpful to identify past human-environment interactions, to investigate the resilience of ecosystems, and to predict and assess impacts for future scenarios, especially in terms of sustainability. Major research questions include the coevolution of natural environments and human societies, the sustainability of former land use practices, and how past land use may have significantly altered present-day environments by irreversible changes.

Research in land use history covers several scientific disciplines, ranging from historical and agricultural geography to archaeology and paleoecology, and involves both natural and social sciences. Land use history can be investigated using several approaches. Recent changes can be documented by remote sensing techniques such as satellite images or aerial photographs. Further back in time, information is provided by written sources, location names, historical maps, and early land surveys. Beyond these historical sources, natural archives such as peat deposits, colluvial soils, and lake sediments can be used to reconstruct past environmental conditions and, thus, land use history. Pollen, charcoal, and macrofossil analyses of such sediments provide valuable information about the past composition of vegetation. Decreasing tree pollen and the appearance of weed and cereals in the pollen spectra indicate human cultivation. Minerogenic layers in such sediment sequences can point to periods of greater soil erosion. Additional indications of former land use practices include specific geomorphologic and pedologic features such as terraces, irrigation ditches, and plough horizons.

Examples of Land Use History

The magnitude of land use varies depending on the time period and the geographical area under consideration. Thus, land use history is

intrinsically complex, and there are few global-scale estimates of long-term changes in land use. The following three examples illustrate the position of land use history in the intersection of climate and human society and its importance for present and future environments.

Early Agriculture

Approximately 10,000 yrs. (years) ago, sedentary farming independently evolved in Central America, China, and the Middle East. From the latter, it gradually spread into Europe, Northern Africa, and Western Asia. Shifting cultivation developed as an alternative cultivation method in regions with conditions unsuitable for permanent agriculture, especially the tropics. It is debatable whether this early human land use could have interfered with the climate system by the release of greenhouse gases, which may have prevented a natural cooling trend that would have otherwise started 8,000 yrs. ago. Some of the critical aspects necessary to verify this hypothesis in models are related to land use history—for example, reliable estimates of the area of deforestation, the amount of livestock grazing, or the loss of soil carbon caused by long-term land degradation.

Medieval Europe

Around AD 700, increasing population in Central Europe caused a continuous decline in forest cover as woodlands were cleared for agriculture (Figure 1). During an extreme rainfall event in the 14th century, increased runoff from the deforested land caused devastating floods and soil erosion. The cascading effects (e.g., famines caused by reduced agricultural production) and additional catastrophes such as the bubonic plague and warfare resulted in a significant decrease in population and thus land use. This lasted for more than a century before the situation stabilized in the 16th century, partly due to an increase in agricultural productivity through the adoption of new techniques, for example, elimination of the fallow period in a three-field crop rotation, selective manuring, and introduction of new crops.

European Settlement in North America

Starting in the 18th century, much of Eastern North America was cleared for agriculture and

Figure 1 Land use change (shaded areas) and soil erosion (red line) in Central Europe (excluding the Alps)

Reprinted with kind permission of Springer Science and Business Media.

grasslands by the European settlers. In Massachusetts, 60% to 80% of the land was under cultivation around the mid 19th century. Natural reforestation due to the abandonment of farms began around AD 1850 and continued into the 20th century, owing to the relocation of agriculture to the Midwestern states and rural populations moving into cities. Whereas the forest cover was closely linked to agriculture during the previous centuries, the situation changed in the 1950s, when woodlands partially decreased again as a result of residential and industrial developments. These landscape changes represent broad-scale disturbances of presettlement ecosystems; the effects of land use on soil erosion rates and eutrophication of aquatic systems as well as the

persistent impact on modern vegetation, soils, and climate have been demonstrated in several studies.

LAND USE PLANNING

Land use planning is a process by which land uses are allocated through legal and political decision making; it is a process by which space is made, and it reflects and distributes power over land and people. Land use planning in the United States takes place within a legal framework that reflects the nation's founding as a republic that stood against feudal traditions, instituting the free holding of land by individuals, regardless of background and/or status. There are several nested and tiered layers of law and regulatory delegation of powers over land use by government, which structure how land use can be planned. This entry focuses on land use planning in the United States, which is illustrative of land use planning processes in many other societies.

Constitutional Requirements

The Bill of Rights of the U.S. Constitution contains two important amendments that shape that country's land use planning: the Fifth and the Fourteenth. The Fifth Amendment includes a clause that prohibits the taking of private property for public use without just compensation. The Fourteenth Amendment requires states to provide equal protection and due processes to protect life, liberty, and property for all citizens under law. These requirements mean that the state cannot condemn land for public purpose

without compensating the landowner at fair market value and it cannot act arbitrarily to favor one landowner or entity over another.

Article 6 of the U.S. Constitution can also affect land use planning. It declares that federal law prevails over state laws unless federal law violates the U.S. Constitution. The federal government can invoke Article 6 for land use planning issues that affect land across states or promote the public interest, such as power transmission line easements, placement of toxic waste dumps, and other facilities that are deemed in the national interest and for which the federal government can override state and local decision making. A prime example of this power is the siting of the high-level nuclear waste repository in Yucca Mountain, Nevada, by the federal government despite strong opposition in Nevada. After years of controversy, the Obama administration announced in March 2010 that the U.S. Department of Energy was withdrawing its pending license for the Yucca Mountain repository.

State and Local Authority

The U.S. Constitution delegates all powers not necessary to the functioning of the federal government to the states. Authority is then delegated from states to cities and counties, which are granted authority over land use by the states. The U.S. Constitution does not mention local governments; local governments are the legal creations of states, which then delegate authority to them. Over time, cities gradually developed independent status from state legislatures, though the extent and type of municipal land use authority depends on whether the city is a general-law city or a home rule (charter) city. Many states have both types of cities. General-law cities are bound by the state's general law, regardless of whether the subject concerns a municipal matter. In this case, state law describes the city's form of government, management structure, personnel matters, election rules, taxation, contracting, and so forth. State statutes prescribe the powers and duties of general-law cities. If something is not allowed by state law, a city cannot do it.

Home rule (charter) cities look to the state's constitution and statutes to determine what they may not do. Such cities have the inherent authority to do just about anything that qualifies as a public purpose and is not contrary to the constitution or laws of the state. They have inherent powers, that is, powers possessed by a city without having been specifically granted by the state. They are free to choose their form of government; for example, they can choose whether the city has a strong mayor who appoints agency directors, whether there is a large or small city council, whether elections are held by district or at large, and what the terms of office are, among other powers. These rules are codified in a charter that is approved by vote of the local citizens. Amendments must also be approved through election.

Each state has its own tax system, but local taxes typically include property taxes, sales taxes, and taxes and/or fees for services such as police, fire, and schools, among others. States and localities also receive intergovernmental transfers from the federal government. The U.S. Constitution and the relationship of cities to their state provide the foundation for land use planning in the country. Outside cities, counties also engage in land use planning, which is also constrained by the U.S. Constitution and state mandates.

Planning, Zoning, and Local Economic Development

The Industrial Revolution of the 19th century caused unprecedented and unorganized urban growth. Housing was located in or adjacent to industrial facilities, building heights and densities were unregulated, and the urban environment was frequently insalubrious. As a result, between 1900 and 1916, land use planning tools began to be developed, including zoning that segregated uses to protect human health and to create orderly economic development patterns. Zoning, as an allocation of space, determines what uses go where and what adjacencies are created. Zoning is also therefore a tool that local governments can use to define the character of a community and its development path. Communities that zone much of their land for industrial

uses will have a very different character from those that harbor single-family neighborhoods. How land is zoned also directly affects local revenues, in the form of a range of taxes. Zoning and land use are thus the key components of a city's powers of exclusion and inclusion, of its wealth and social composition.

As such, the power over land use creates a very strong relationship between local decision makers and economic interests. This relationship, dubbed by Logan and Molotch as the "urban growth machine," is one in which, for local government, land is the principle asset through which elected officials shape the character and revenue stream of the locality. It relies on coordination and planning with local business interests whose activities on the land create not only local wealth, through taxes and fees, but also jobs and prosperity. Local institutions are therefore characterized by a close relationship between politicians and businessmen to enhance the commercial public and private interests of localities. Cities—and increasingly counties—to remain prosperous, compete for revenue-generating land uses and plan their land for the uses they consider will yield the highest revenues. Thus, planning becomes increasingly a function of economic development policy.

Counties face many of the same pressures and also plan land use in unincorporated areas. Counties also have additional responsibilities, as they are the state's designated representatives at the local level, providing health and welfare services in addition to planning services. They, too, compete for revenue-generating development through their land use designations and become an additional competitor in the race for economic development.

Environmental Issues

Over the course of the 20th century, with the rise of the environmental movement, the question of land use has at times been seen as intrinsic to environmental preservation and quality. Tensions about how much authority the federal government should exert in land use planning for environmental protection and orderly land development versus state and local authority have

characterized the relationships among these levels of government since the federal government reserved the public domain. Rather than planning rules, the federal government has created incentives to encourage thoughtful planning of critical resources. For example, the federal Coastal Zone Protection Act in 1972, reauthorized in 1996, provides annual grants to states to develop coastal zone management programs.

At the state level, such tensions have also been prevalent. California's 1972 Coastal Protection Act went further and created a new agency in charge of land use planning along the coastal zone, up to 1 mile inland, with regional agencies throughout the state. The authority of this agency has been contested ever since. Environmental concerns also led to the creation of the landmark 1973 Oregon statewide land use planning law: Oregon Land Use Act (Senate Bill 100). Under that program, all cities and counties adopted 19 comprehensive plans that met mandatory state standards. They address land use, development, housing, transportation, and conservation of natural resources. The law was contested in 2004, when Measure 37 was approved, requiring compensation for property owners whose property value was reduced by local zoning for agricultural land protection or one of the other 19 planning goals. Measure 37 was passed, based on the claim that Senate Bill 100 infringed on private property rights, and more than 7,000 claims for compliance payments or land use waivers were filed, totaling more than \$250 million. It became clear that if local governments' land use authority were curtailed, there would never be enough revenues to pay for the alleged takings. In 2007, voters overturned Measure 37, realizing that it would severely restrict the state and local governments' ability to zone land and that haphazard economic growth would result.

Another result of the 1970s environmental movement was the passage of the Endangered Species Act (ESA) in 1973. Originally intended by Congress to protect charismatic animals such as golden eagles and grizzly bears, with rapid population growth and urbanization in places such as Southern California, a biodiversity hotspot, the ESA has affected local land use planning. The ESA's purposes include providing a

means whereby the ecosystems on which endangered or threatened species depend may be conserved. The ESA has evolved into a land use law, though indirectly, by providing environmental groups with a powerful tool to challenge projects that might endanger the existence of species and their habitats. This has led to the development of plans to ensure the survival of species. In California, this process is reinforced by the California Environmental Quality Act (CEQA), which requires environmental impacts statements for all new developments.

The ESA has, in some places, become a forcing mechanism for large-scale land use planning, determining which lands will remain in permanent open space and which lands can be developed. These are often complex, lengthy, and expensive negotiation processes whose ultimate success depends on many factors, including the constellation of local economic interests, elected officials, and the permit process, which involves layers of government agencies and officials. Nevertheless, short of Oregon-style statewide planning, habitat conservation planning under the ESA has been a step toward regional planning but occurring only where there are endangered species.

In addition to the ESA, there are other emerging considerations that are starting to affect the traditional local purview over land use planning. In places facing possible water shortages, state legislatures have begun to look at the relationship between land development, water availability, and the water intensiveness of land use. Regulations are beginning to emerge to ensure sufficient water supplies for new development by scaling the land use appropriately. Climate change is also a new factor that may encroach on local authority, as agencies begin to better understand the relationship between urban form (land use) and greenhouse gas emissions.

Conclusion

There is an intimate relationship between land use and local economic interests that is longstanding in the United States and that is inscribed in private property protections under the U.S. Constitution. Elkin describes the United States as the

Commercial Republic, reflecting these close ties. However, the unanticipated impacts of human activities, such as the depletion of water resources, impacts on biodiversity, and climate change, are creating new dimensions to land use planning that cannot be readily addressed within the existing framework. In addition, changing revenue sources and structures are also beginning to affect land use decision making, as land use has historically been the foundation for local government-funding streams. At this historical juncture, land use planning rules and conventions are inadequate for changing climatic conditions and the changing demographic profile of the nation. Yet constitutional constraints, entrenched views of private property rights, and the belief in local control over local land use will make future evolutions complex and difficult.

LAND-WATER BREEZE

The land-water breeze is a localized land-atmosphere phenomenon that arises due to the differential heating of water and land surfaces. This differential heating creates local atmospheric circulations (i.e., breezes) that can strongly affect weather and climate in coastal regions. The land-water breeze and the differential heating of land and water surfaces are recognized factors in explaining temperature patterns and the differences between coasts and inland locations.

A water breeze, more often called a *sea breeze*, is a cool breeze blowing off an ocean or body of water onto the adjacent land. This breeze is created by the temperature contrast between the cool body of water and the warm land surface. The temperature contrast is usually greatest during warm, sunny afternoons in spring or summer, as the ocean temperature remains cool but the incoming solar radiation heats the land surface. The increased temperature and radiation at the land surface results in the warming of the air (atmosphere) above the land. Because warm air is less dense than cool air, the warm air expands and rises. This upward movement of air creates a local increase in air pressure aloft as the air "piles up" and creates a pressure gradient aloft between the land and ocean locations (Figure 1). Air flows from the local high pressure to the local low pressure. The removal of air above the land surface then creates a local surface low pressure, and the flow of air toward the ocean creates downward-moving air and a high pressure near the surface. Surface air flows from the high pressure over the ocean to the low pressure over the land, carrying the cooler ocean air with it, resulting in the water or sea breeze. This local circulation forms a convection cell or convection loop.

In the land breeze, the situation is reversed. Land breezes occur mainly on cool, clear nights during the fall and winter, when radiational cooling is strongest and water temperatures are fairly warm. At night, the land surface and the atmosphere above it will cool off due to radiational cooling, while the ocean temperature remains relatively constant. As the air above the land surface becomes denser, the atmospheric column contracts, forming

Figure 1 Land-water breeze: surface and aloft circulation

Source: Author.

sinking air and a local area of high pressure. Again, the upper air (aloft) is affected by the heating and cooling of the surface. As the air sinks over the land, a low pressure is created aloft, and a high-pressure center forms over the water. Air aloft flows onshore, which creates further vertical sinking over the land. The onshore flow produces vertical rising over the ocean, creating a local low pressure. The land breeze is produced by offshore flow between the land high and the ocean low pressure.

LANGUAGES, GEOGRAPHY OF

Language (in contrast to speech) may be understood in several ways: (a) as a means of organizing thought; (b) as a way of communicating, that is, producing and sharing meaning; and (c) as a vehicle for bringing the world into consciousness, that is, of converting sensations into perceptions. Language is a system of symbols through which cognition is structured, and it is intimately wrapped up in individual and collective identity. It is impossible to understand the world without it. Language is thus simultaneously a psychological, social, and cultural phenomenon. In many countries (e.g., Belgium, Canada), languages have deep political significance as well and may be the source of ethnic strife. Because languages are unevenly distributed across space, they are also inherently geographical.

Because languages are semantically and historically related to one another, it is common to group them into families of varying sizes. Linguists and cultural geographers typically maintain that there are roughly eight major language families as well as several others termed *isolates*.

Indo-European Languages

By far the largest and most widespread of the major language families is the Indo-European, a group first identified by the famous linguist William Jones, a British judge stationed in India, in the 18th century. Starting with the migrations of the so-called Aryans around 1500 BC to 2000 BC, perhaps as a result of their domestication of the horse, Indo-Europeans moved in two directions from their homeland near the Caucasus Mountains. (Indeed, names such as *Ireland* and *Iran* are derived from the name of this tribe). One group moved east into Northern India, their languages becoming the basis of the Sanskrit-based Indic languages, such as Hindi, Bengali, Urdu, Gujarati, Bihari, Marathi, Sinhala, and Nepali. Others remained in the Middle East, where their languages eventually became the Indic family, including Farsi (formerly Persian), Kurdish, Armenian, and Pashto in Afghanistan. The other major branch of Indo-Europeans moved into Europe, where they diverged into several groups. The languages of these groups include the Latin-based Romance languages (Italian, Spanish, Portuguese, Catalan, French, Romansch, and Romanian), which arose during the disintegration of the Roman Empire. Greek and Albanian form separate categories in their own right. Farther north, the Germanic languages include German, Dutch, the Scandinavian tongues, and English. Celtic, an early branch once widespread throughout Western Europe, today consists of Scottish and Irish Gaelic, Welsh, Breton in Western France, and extinct tongues such as Cornish; this branch is in danger of disappearing. In Eastern Europe and Russia, the Slavic branch includes Polish, Russian, Ukrainian, Czech, Slovak, Slovenian, Serbo-Croatian, and Bulgarian. The Baltic group of Lithuanian and Latvian is another branch.

With the expansion of Spanish, Portuguese, French, and British colonialism, Indo-European languages were carried throughout much of the world, becoming dominant throughout the New World, Australia, and New Zealand (Figure 1). Today, about half of the world speaks an Indo-European tongue of one sort or another. English, in particular, empowered and diffused by the British and American empires, has become the *lingua franca* of more people than any other tongue (when second-language speakers are included).

English is unquestionably the world's dominant language in commerce, trade, scholarly publications, airlines, international finance, and tourism.

The rise of the nation-state as well as the invention of printing had enormous effects on the social and spatial structure of language. One dialect—typically that of dominant elites, whether in Tuscany, London, Madrid, or Paris—became privileged over others, expanding into national languages, annihilating local differences in vocabulary and pronunciation but integrating diverse groups linguistically into a common group. The newly printed languages were fundamental for the emergence of a national consciousness because they geographically connected speakers of, for example, local varieties of “Englishes,” “Spanishes,” and “Germans” and made known to them the existence of others who shared the same language group. These newly printed languages forged dialects together into national languages. Printing thus constituted a prime dimension in the time-space compression that created modern nation-states.

Afro-Asiatic Languages

A second major language family is Afro-Asiatic, which extends across the Middle East and North Africa (Figure 2). This group includes most of the extinct or nearly extinct languages of the ancient Middle East, such as Canaanite, Phoenician, Assyrian, and Aramaic (of which pockets survive). The dominant branch of the Afro-Asiatic family is Semitic, which includes Arabic (with numerous dialects) and Hebrew, nearly extinct as a spoken language until it was revived by the Zionists at the end of the 19th century. Other branches include Berber, widespread in the Maghreb, and Kushitic, the dominant family of Ethiopia (i.e., Amharic) and Somali.

Ural-Altaic Languages

Ural-Altaic, also sometimes called Finno-Ugric, constitutes a third family. The origins of this group, probably near the Altai mountains of Mongolia, are lost in prehistory. It is likely that speakers of these languages are descendants of several waves of migration that generated populations that continue to speak loosely related tongues stretched across Eurasia (Figure 3). Finnish and Estonian constitute one example; Hungarian, the

language of the Magyar who settled in Eastern Europe in the 8th century, is another. A third branch is the Turkic languages, which all emanated from the Turkish migrations into Central Asia and Anatolia in the 9th and 10th centuries; the remaining Turkic languages include Turkish, Azerbaijani, Kazakh, Uzbek, Turkmen, Kyrgyz, and Uighur in Western China. Yet another branch is Mongol and Manchu, formerly spoken in Manchuria but now extinct, as are the indigenous tongues of Siberia, such as Samoyed and Tungic. Finally, although it is controversial, many linguists assign Japanese and Korean to this family as well.

African Languages

Africa south of the Sahara desert is a complex mosaic of tongues from several language families. In addition to the Afro-Asiatic languages in the north (Arabic, Berber) and in the Horn of Africa (Amharic, Somali), it has smaller families such as the Nilo-Saharan and, in Southwest Africa, the famous click languages of the Khoisan family (e.g., !Kung). However, the bulk of the many languages spoken throughout this vast region fall

under the Bantu or Niger-Kordofanian language family, which includes thousands of tongues (Figure 4). Arising from the migrations of agriculturalists from Central Africa around the time of Christ, this family includes languages as diverse as Mande in Western Africa, Kikuyu in Kenya, and Tswana, Nbele, and Zulu in Southern Africa. Along the eastern part of the continent, Swahili has long formed a lingua franca, a trade language that combined words of different languages, including some from Arabic.

Asian Languages

In Eastern Asia, the Sino-Tibetan language family is the most commonly spoken group (Figure 5). Common to this group is the use of tones (although these are found in some African languages, too), in which pitch forms part of the meaning of the word. This family includes Chinese, which embraces a variety of languages that are not mutually intelligible but use a common writing system (a feat only made possible with a pictographic writing system, not an alphabet). Chinese includes Mandarin, the dominant language of Northern China (and the

most commonly spoken language at home in the world) and close to a national tongue (Szechwanese is a dialect), as well as Cantonese and less well-known ones such as Shanghainese, Wu, Hakka, and Fukienese or Taiwanese. This group also includes Tibetan and, because of Tibetan migrations down the Irrawaddy River, Burmese.

A sixth major family is the Malayo-Polynesian, a diverse group that extends across much of south-east Asia into the islands of Polynesia and Micronesia (Figure 6), thus including Hawaiian and New Zealand's Maori. Originating among tribes in Taiwan, this group includes the Malay languages of Malaysia and Indonesia (each with countless dialects) and the numerous tongues of the Philippines, of which Tagalog is the best known. Around AD 500, Indonesian sailors crossed the Indian Ocean and settled in Madagascar, making the language Malagasy part of this family.

Other Language Families

Several other families are worth noting. Southern India is home to a sizable population who do not

speak Indo-European languages but the Dravidian tongues Tamil, Telugu, Kannada, and Malayalam. The Indochinese peninsula is home to two distinct language groups, Austro-Asiatic (Vietnamese, Cambodian) and Thai-Kadai (Thai, Lao). The Aboriginal peoples of Australia and Papua New Guinea, who constitute 1% of the world's population, speak 20% of the world's languages in an enormously diverse group often called Indo-Pacific. The Americas were home to a huge range of indigenous languages prior to the mass demographic and cultural extermination unleashed by the Europeans: More than a dozen families existed in North America (e.g., Iroquoian, Siouan, Salishan, Athabaskan, Mayan) and in South America (Andean, Chibchan, Macro-Carib). Finally, isolate languages such as Basque, with no surviving relatives, and Kartvelian tongues such as Georgian, continue to survive.

Language Death

Today, there are roughly 5,000 to 6,500 languages remaining in the world. Most, however, have very

few speakers, often numbering only in the dozens, and are not written. The total number was much larger in the past and has been steadily declining for centuries. The rise of the nation-state often led to a deliberate homogenization of cultures and dialects, and today, globalization and national school systems have contributed to the decline. In the Americas, disease, genocide, government-run boarding schools in the United States, and cultural assimilation annihilated large numbers of languages. Today, 96% of the planet speaks one of the top 20 languages, and many observers predict that 50% of all languages will disappear within the next century (one every 2 weeks). This decline represents a crisis in cultural diversity that deprives humanity of the rich ways of viewing the world inherent in the multiple different languages.

Language and Geographic Analysis

Finally, in addition to the geography of languages, geographers have long been interested in the role of language in the representation of space. Because language structures and mediates thought, it plays an enormous role in how discourses about the world are organized. Language as a structured symbolic system has figured prominently in philosophy for decades, including varied analyses by authors such as Ludwig Wittgenstein, Benjamin Whorf, Jurgen Habermas, and various poststructuralist authors (e.g., Jacques Derrida), who interpret the world through the lens of discourse. In this light, language is not simply a medium for communicating but an obstacle as well, a force that enters into the making of social and spatial reality. For humanistic geographers, language is a window into the structure of human consciousness and spatial perception, for language shapes how human beings give meaning to space and their sense of place. Language became a central topic in the intersections between geography and literary criticism, including the analysis of landscape as texts. For Gunnar Olsson, the limits of language amounted to the limits of understanding. Feminists have emphasized the gendered nature of language and how it helps to reify or to challenge gender roles and performativity. For followers of Michel Foucault, language is constitutive of ideology and discourse and thus is always intimately associated with power and the social production of subjects. For postmodernists, languages always oversimplify

the world, for reality is more complex than any language can admit. A broad consensus emerging from these various perspectives is that all worldviews are inherently and necessarily partial, contingent, and situated in context. Such lines of thought have enormous implications for the ways in which truth is conceived (e.g., as a mirror of the world or as part of a situated worldview) and how explanation is justified. Language is thus a deeply epistemological phenomenon, for humans do not simply use language, they are in turn shaped by it.

LA NIÑA

La Niña refers to anomalously cool central to eastern equatorial Pacific surface waters. These climate events occur every 2 to 7 yrs. (years) and last anywhere from about half a year to 3 yrs., with peak strength in the boreal winter season. *La Niña* is also often synonymous with the “high” phase of the Southern Oscillation, with the *El Niño* comprising the “low” phase. During the high phase, sea-level pressure is higher than normal over the Eastern Pacific (e.g., Tahiti) and lower than normal over the Maritime Continent (e.g., Darwin, Australia). *La Niñas* have a large impact on certain regional climates but have not been extensively studied in geography or the atmospheric sciences.

While *El Niño* (“little boy”) has been part of the Peruvian vernacular for centuries, *La Niña* (“little girl”) was coined by George Philander in the mid 1980s, implying its opposite nature. This definition coincided with a *La Niña* event from

October 1984 to September 1985, which followed on the heels of the very strong 1982–1983 El Niño and marked the first cold period since the mid 1970s. Recent La Niña events, as defined by the National Oceanic and Atmospheric Administration, have occurred in 1988–1989, 1995–1996, 1998–2001, and 2007–2008.

La Niñas often follow strong El Niños. According to the delayed-oscillator theory, “warm” eastward-traveling Kelvin ocean waves and “cold” westward-traveling Rossby ocean waves are generated by westerly wind stress from the El Niño, and when these waves reflect at the boundaries of the Pacific and recross the ocean, their damped signal forms the subsequent La Niña. In general, La Niñas tend to be weaker than their climatological brothers, with the largest temperature anomalies reaching about -2.0°C (Oceanic Niño Index). The basic climate system of the equatorial Pacific is warm, deep waters in the west and cool, shallow waters in the east with easterly surface winds. Since La Niña simply amplifies this base state, it is much more difficult to get strong anomalies than when there is a reversal of the system during an El Niño. La Niñas also affect the biogeography of the Pacific. The shoaling of the Eastern Pacific Ocean mixed layer is accompanied by vigorous upwelling. More nutrients are brought to the ocean surface during La Niña, causing widespread primary productivity blooms, which support a diverse marine ecosystem.

La Niñas change the global atmospheric circulation. While El Niños thermodynamically increase the instability of the tropical atmosphere, La Niñas concentrate convection over the Maritime Continent, which receives copious rainfall. Thus, the zonal atmospheric circulations, or Walker Circulation, are dynamically altered, with much of the Pacific dominated by subsidence and dry conditions. These changes in the Pacific are communicated to the rest of the globe through “teleconnections”—a combination of variations in the meridional Hadley Circulation, “atmospheric bridge” mechanisms, and atmospheric Rossby wave trains (Figure 1).

In boreal winter over the United States, the southern states are anomalously dry and warm, the northeast is wet and cool, a band from the Pacific coast of Alaska to the Northern Great Plains is cool, and the Ohio Valley is wet. Also in this season, northeast Brazil tends to experience

Figure 1 Example of an atmospheric Rossby wave train (anomalous high- and low-pressure centers and jet streams) associated with La Niña

Sources: Google Earth and the National Oceanic and Atmospheric Administration.

wetter (cooler) conditions than normal. Japan and West Africa are anomalously cool, and southeast Africa is wet and cool. Conversely, parts of equatorial Africa are drier than normal. In boreal summers, there is no La Niña signal in the extratropical Northern Hemisphere, but West Africa remains cool, the Caribbean becomes cool and wet, and most of South Asia is cooler than normal, with India also becoming wetter than normal. Also in this season, the South Pacific island nations experience warm conditions, the west coast of South America is cool, and Argentina, Uruguay, and Southern Brazil become dry. Just as El Niño and La Niña are near mirror images in the Pacific Ocean, many of the teleconnections are seen as opposites as well. However, some scientists dispute this linearity assumption. Finally, generalities about the impacts of La Niña are problematic because every event is different. Figure 2 shows the evolution of global precipitation and temperature anomalies during the strongest La Niña in the satellite era.

For reasons not yet completely understood, the El Niño-La Niña cycle undergoes decadal-scale variability tied to the Pacific Decadal Oscillation

Figure 2 Surface temperature and rainfall anomalies, based on 1951–1980 and 1987–1996 data, respectively, averaged over 3-month seasons during 1988

(PDO). Recent trends in the PDO suggest that the mid 2000s could mark a regime shift into a 30-yr. period where La Niñas will dominate over El Niños and may explain the lingering 2007–2008 La Niña. The last time the PDO pendulum swung to La Niña was between the 1950s and 1970s (before the term *La Niña* existed). There is also some controversy as to whether global warming may lead to a permanent La Niña-like state. In 1996, Amy Clement and coauthors first postulated that if a uniform heating was imposed on the surface of the ocean, upwelling could regulate the warming. Known as the *ocean dynamical thermostat* mechanism, the Eastern Pacific (where upwelling occurs) should warm less fast than the Western Pacific, and the zonal temperature and pressure gradients should increase. This would lead to stronger easterlies, inhibiting westerly disturbances and the formation of El Niños. This theory has been corroborated by some climate models and observations but not others, so further study is needed.

Even though the global impacts of La Niñas are equal in scope to the impacts of El Niños, La Niñas have not received the same attention in the scientific community. A search for “El Niño” in journal article titles and abstracts from a large publication database uncovered 9,573 records, but “La Niña” could only muster 1,645. This disparity must be rectified with greater research emphasis on La Niña, especially since it may play an important role in Earth’s climate in the near future.

LAPSE RATE

Lapse rates are the average changes in temperature at different levels in the atmosphere. Four different rates are environmental, normal, dry adiabatic, and wet adiabatic. Each is applied in specifically different situations. The changing temperatures affect the humidity and the climatic patterns. Types of lapse rate, their applications, their relationship to cloud formation and atmospheric lifting, and the environmental hazards are discussed here.

The environmental lapse rate is the actual change in air temperature with altitude at a specific place at a specified time. The temperature depends on current micro- and macro-meteorological conditions. In general, temperatures are expected to decrease with altitude through the troposphere, the lowest temperature zone of the atmosphere. However, temperature variations occur, and the actual situation makes the environmental lapse rate. For example, this might be measured with a thermometer as a balloon rises vertically from the surface through the air.

The normal lapse rate is the mean of the environmental lapse rates. Considered to be 6.5 °C/1,000 m (meters) or 3.5 °F/1,000 ft. (feet), this value is used both to estimate the temperature at a higher elevation, such as for an airplane flying overhead, and to compare temperatures between locations at different elevations, for example, San Francisco, California, near the coast, and Denver, Colorado, about a mile higher.

The normal lapse rate is closely related to the greenhouse effect. Because the troposphere is predominantly heated by the absorption of terrestrial radiation, more of this Earth radiation is trapped near the surface than reaches the higher levels. So temperatures near the surface are generally warmer than in layers aloft, and this average temperature differentiation is the normal lapse rate.

The dry adiabatic lapse rate applies to temperature changes in an unsaturated parcel of air that is physically changing elevations. The atmospheric pressure surrounding a parcel of rising air decreases, so it expands and cools. Thus, the rate of temperature change is greater than the normal lapse rate. The dry adiabatic lapse rate is about 10 °C/1,000 m, or 5.5 °F/1,000 ft.

Figure 1 Lapse rates example diagram

Source: Author.

As unsaturated air cools, the relative humidity rises, and the temperature approaches the dew point temperature. Once cooled to the dew point temperature, net condensation exceeds net evaporation, and latent heat stored by the moisture is released to the environment in a warming effect. Thus, a parcel of rising saturated air will not cool as rapidly as rising unsaturated air. The result is the wet adiabatic lapse rate of 5 °C/1,000 m or 3.0 °F/1,000 ft. This rate depends on the amount of condensing moisture.

Application of Lapse Rates

Typically, a mountain example is used to model the temperature changes of the air. The normal lapse rate is used if temperatures are being compared from one location to another or to eliminate the impact of elevation on the temperature. The

equivalent sea-level temperature results from calculations to remove the impact of elevation and convert the temperature to zero elevation units. The dry adiabatic lapse rate applies while the temperature remains above the dew point temperature moving up the mountain. On reaching the dew point temperature, when the air becomes saturated and the net condensation begins building clouds, the temperature drops at the wet adiabatic lapse rate as it continues to rise. Air moving back down the leeward side of the mountain will warm at the dry adiabatic rate (Figure 1).

If condensation has occurred on the windward side of the mountain, the subsiding air on the leeward side will be warmer and drier than the air at the same elevation on the windward side, because of the moisture removed by condensation and the latent heat released to the air. The lower humidities and higher temperatures on the leeward side

of a mountain range produce a rain shadow effect, which accounts for some regions' arid and semi-arid climates.

Lapse Rates, Air Parcel Movement, and Atmospheric Hazards

Lapse rates are very important for understanding cloud formation, because the rate of temperature change in the moving air affects the level at which condensation begins. Four processes cause air to rise: (1) convergence occurs when winds meet, as at the intertropical convergence zone (ITCZ) and the polar front; (2) convection makes air rise because of density differences; (3) air rises at frontal boundaries as the warmer, lighter air overrides the cooler, heavier air; and (4) orographic lifting forces air over a topographic barrier, such as the mountain in the previous illustration. Regardless of the cause, the rising air will cool as the decreased atmospheric pressure results in expansion.

The lapse rates are averages, but in the absence of actual measurements, they are helpful in predicting atmospheric conditions and modeling air

parcel behavior. Atmospheric stability depends on the relationship between the environmental lapse rates and the adiabatic lapse rate. A parcel of air forced to rise for any reason will move through air layers, which changes the temperature at the environmental lapse rate. If this local temporal rate is less than the dry adiabatic lapse rate, the rising air will be warmer than the surrounding air. It will resist vertical movement and thereby will be stable. However, if the environmental lapse rate is greater than the dry adiabatic lapse rate, the rising air will end up warmer and lighter than the surrounding air. This situation yields instability and invokes continued lifting of the air. Extreme instability is associated with strong thunderstorms and tornado development. Intermediate situations may yield conditional instability (Figure 2).

In some situations, the environmental lapse rate may show a temperature increase with height. Such a layer is a temperature inversion, and due to the stability provided by these warmer layers, atmospheric mixing becomes limited. Pollutants may become concentrated below this warm layer

Figure 2 Atmospheric stability and instability

rather than thoroughly dispersed. Air quality advisories, alerts, and warnings may be issued, directed especially at persons with respiratory problems and other health risks (Figure 3).

Lapse rates control the patterns of condensation, air movement, and air quality. Although lapse rates may be variable, their inclusion in atmospheric models aids prediction and forecasting.

LATENT HEAT

Latent heat is the energy absorbed or released in the form of heat by a substance when it changes its physical state (i.e., solid, liquid, or gas). The change associated with the solid-liquid transition is called the *latent heat of fusion* (melting), and the change associated with the liquid-gas transition is called the *latent heat of evaporation* (boiling). The International System of Units (SI) for latent heat is joules per kilogram or kilojoules per kilogram (kJ/kg). Because 1 cal/g (calorie per gram) = 4.185 kJ/kg, for pure water, the latent heat of melting of 65 cal/g = 272 kJ/kg and the latent heat of evaporation at 10 °C of 425 cal/g = 1.78×10^3 kJ/kg. It is important to note that the amount of latent heat involved in a process depends on the temperature at which the process is occurring.

Latent Heat in the Ocean Heat Budget

Latent heat in the ocean results from evaporation at the ocean surface. As water changes from liquid in the ocean to vapor in the atmosphere, the ocean loses energy in the form of the latent heat of vaporization, and the atmosphere gains heat when the vapor condenses. Since water vapor pressure depends on temperature, sea surface temperature is an important parameter in determining the latent heat flux. The oceans effectively capture a major portion (about 50%) of the sun's radiated energy and transfer much of it to the atmosphere as latent heat of vaporization and as radiation. The rate of heat flow is expressed in joules per second (J/s) per square meter, or watts per square meter (W/m^2) ($1 \text{ W} = 1 \text{ J/s}$).

The analysis of atmospheric modeled data for the 1958–2001 period in the Mediterranean Sea reveals that the time-mean latent heat is negative for the whole domain, with a mean value of -88 W/m^2 . Its temporal mean ranges from -20 W/m^2 in the Alborán Sea (Western Mediterranean) to -125 W/m^2 in the Levantine basin, Aegean Sea, and Gulf of Lions. Regarding its seasonal cycle, the minimum value (-125 W/m^2) is detected by mid November and the maximum (-51 W/m^2) by mid May. The amplitude of the seasonal cycle is 37 W/m^2 . In terms of total heat

Figure 1 Spatial distribution of the temporal mean of latent heat (in watts per square meter) over the Mediterranean Sea using 44 years (1958–2001) of atmospheric model data. The main regional subbasins are indicated.

Source: Adapted from Ruiz, S., Gomis, D., Sotillo, M. G., & Josey, S. A. (2008). Characterization of surface heat fluxes in the Mediterranean Sea from a 44-year high-resolution atmospheric data set. *Global and Planetary Change*, 63, 258–274.

budget, which takes into account all the components (latent heat, sensible heat, long-wave radiation, and shortwave radiation), there is a practical cancellation (-1 W/m^2) of the heat flux components for the whole period mentioned above (see Figure 1).

In conclusion, *latent heat* is one of the most variable terms in the global heat budget, and it is crucial at short (e.g., heavy precipitation) and longer timescales (e.g., interannual variability). New international long-term experimental programs aim at better quantification and understanding of the hydrological cycle, and particularly of latent heat. Estimates of latent heat will improve with increasing high-resolution in situ and remote data (ship campaigns, buoy stations, and satellite measurements) and will be useful for both numerical weather prediction models and climate models.

LATITUDE

Latitude is the angular distance of a position from the equator to the nearest pole. However, latitude can acquire different meanings if inappropriately applied to other locations on Earth.

Often expressed in degrees from the equator (positive north and negative south), latitude can

be expressed in a variety of units (radians, grads, semicircles, arc seconds, or mils) and formats (+/– or N/S, to indicate the hemisphere; degrees: minutes and fractional minutes; or degrees: minutes: seconds and fractional seconds). Since one minute of latitude is equal to one nautical mile latitude, tick marks are used on charts as a local graphic scale. Without reference to a specific geodetic datum, latitude values will point to different places on Earth.

If Earth were perfectly spherical, then the general definition for *geographic latitude* might suffice—that is, the angle from the equatorial plane for a line from the center of mass of the spherical Earth to a position. Earth and its gravity field are slightly elliptical in shape. The distance from the center of Earth to the equator is about 21 km (kilometers) longer than the distance from the center to either pole. A consequence of this flattened spherical shape, an ellipsoid of rotation, is that the force of gravity is only exactly toward the center of mass of Earth along the equator or at either pole. Everywhere else, the plumb bob, the bubble level, or the horizon at sea, the references for local level, are affected by the ellipsoidal gravity surface that is perpendicular to a line from a position toward but slightly away from the center of the Earth. The angle between the equatorial plane and a line perpendicular to the ellipsoid surface that passes through a position is the *geodetic latitude*.

There are other latitudes. If one measures position with respect to a sphere that has the same surface area as a reference ellipsoid, the north-south angle is the *authalic latitude*. *Geocentric latitude* is the angle, similar to *geographic latitude* for a sphere, between the equatorial plane and the center of the ellipsoid. There is a *parametric* (or *reduced*) *latitude*, defined as the angle between the equatorial plane and a line from the center of the ellipsoid perpendicular to a surface defined by a sphere tangent to the ellipsoid along the equator or the latitude on a sphere for which the parallel has the same radius as the parallel of geodetic latitude on the ellipsoid through the same point. *Conformal latitude* is a transformation of *geodetic latitude* that allows a conformal mapping using spherical geometry. *Isometric latitude* is proportional to the parallels on an ellipsoidal Mercator projection. *Rectifying latitude* is

the angular distance along a line of longitude from the equator to a point on Earth.

Other latitudes have been defined on Earth, including *astronomic*, *auxiliary equidistant*, *geomagnetic*, *magnetic*, and *transverse*. Surveyors use the word for the y value in a traverse defined in a plane coordinate system.

The importance for geography is that these latitudes are represented by significantly different angles, making their appropriate selection and use critical for positioning and analysis.

LAW, GEOGRAPHY OF

Work on the geography of law focuses on the relationships of law and legal questions to the study of spatial phenomena. Initially developed by a community of scholars working across their respective disciplines, it took shape as a subdiscipline in its own right in the 1990s, usually referred to as *legal geography*, with a modest if growing presence in English language geography. In the broadest terms, work in this tradition posits that there exists a serious and substantial link between law (reflected in legislation, court decisions, administrative tribunals, etc.) and the geographical shape of the social, political, and cultural worlds. This is seen in many different ways, from

the legal organization of international relations down to municipal ordinances governing urban zoning and districting, the placement of public parks and monuments, and the organization of labor protests and panhandling. While the research themes taken up are not radically different from those in other areas of geography, it is the emphasis on the long-ignored connection between law and space that sets apart this field.

Origins

The interface of law and geography has been of interest since at least the 19th century, when geographers, legal thinkers, and ethnologists sought to determine the influence that climate, environment, and social organization might have on the laws governing different “primitive” and “advanced” peoples. For the most part, however, law has developed independently of the social sciences, geography included. Modern legal thought, driven by positivist and normative perspectives, has long understood law as an autonomous and internally coherent sphere of human knowledge. In this sense, it is often held at an intellectual distance from the material world in which it is applied, leaving it “uncontaminated” by political, social, or cultural concerns. This is not a view that encourages cross-disciplinary collaboration, and while geographers do often engage with other disciplines, law has not traditionally been one of them.

In the 1960s and 1970s, however, scholars of law began to rethink the discipline’s isolation from the social sphere. This body of work, typically dubbed “critical legal studies,” sought to challenge orthodox understandings of law, which invariably portrayed the latter as somehow “above” society and removed from politics and culture. Critical legal studies sought to show how, despite claims to the contrary, law naturalizes and normalizes particular kinds of social and political relationships and distributions of power. In the U.S. context, this notion is seen in terms of rights: The way in which the law and the courts address rights to abortion, sexual discrimination, privacy, or free speech are underscored by culturally and socially specific ideas about what makes for a “good” society. By analyzing legislative texts, jurisprudence, and legal

scholarship, critical legal studies has both unsettled existing claims about rights and proposed more radically open-ended approaches to understanding rights under the law.

The break with classical understandings of law initiated by this movement was in turn extremely important for the community of legal scholars and geographers, who, from the late 1980s, started to bring the two disciplines into an interdisciplinary dialogue. If legal scholarship was concerned with rights and the law in a fairly abstract sense, legal geographers were more concerned with examining what Nicholas Blomley dubbed the “law-space nexus,” the ways in which geographical space figures in the legal field and the ways in which law, in turn, shapes space. Property law, for example, posits a set of power-laden spatial relationships between owners, who claim a kind of exclusive jurisdiction over a parcel of land, and nonowners, who enjoy a far more limited set of rights to the properties they may lease, rent, or otherwise use. Governing a society in which private property is seen in these terms requires not just the requisite legal texts but also a range of geographical strategies, from land surveys to cadastral maps, zoning laws, antitrespassing ordinances, and so on.

On a broader scale, international legal texts such as the Geneva Convention on refugees establish and reinforce an organization of global space in which citizens are defined as people who belong to a particular nation-state. Those caught outside their state risk being left in a kind of geographical netherworld, as Viktor Navorski, played by Tom Hanks in the 2004 movie *The Terminal*, discovers. Indeed, the legal geographies of refugee flows can be seen in the proliferation of “stateless” and “lawless” spaces around the world, the most prominent being in Guantánamo Bay, Cuba, where several hundred “enemy combatants” were—from 2001 until the U.S. Supreme Court’s ruling (*Boumediene et al. v. Bush*, June 12, 2008)—held in a legally defined state of limbo, neither fully part of nor fully apart from U.S. legal jurisdiction. Seen as disruptive to the settled geographies of nation-states, refugees, enemy combatants, and other displaced persons present a legal-geographic paradox of sorts, exposing the geographical fault lines and limits of the international legal system.

Emphases

Law, then, is an important way in which the world is given spatial shape, from the global to the local, and scholarship on the geography of law is appropriately diverse in its concerns and approaches. Nonetheless, a few common trends are apparent. First, legal geography is deeply concerned with power and with the spatial organization of relations of power and rule. In particular, law is seen not simply as oppression but as a way of producing commonsense arguments about the world that naturalize the operations of power in and across geographical space. In this regard, it connects to a wide range of work in the social sciences where power is a focal point of analysis. As in critical legal studies, a good deal of work here is explicitly critical in nature, often adopting Marxist or poststructuralist interpretative tools. Second, work in legal geography has focused largely on urban and “local” spatial scales of analysis, such as the community, the region, and the city. Other spatial scales, though, often emerge in analyses of the nested and overlapping jurisdictions that typically govern the law’s application, such as in decisions over whether federal, state, or provincial legal authorities have jurisdiction over workplace safety. Third, while the past two decades or so have seen a proliferation of case studies that deal with the geography of law, relatively little work has been done on the subfield’s methodological frameworks. This void contrasts sharply with other areas of human geography, economic and social geography in particular, where the same period has witnessed a relative explosion in debates over these questions. The subfield, in short, is fluid and dynamic, providing little in the way of orthodoxy or canonical texts through which to anchor the reader.

The remainder of this entry proceeds by identifying three broad approaches that have found their place within the geography of law. These are neither exhaustive nor mutually exclusive categorizations, and scholars who do the work described below might not all describe themselves as legal geographers (although some certainly would). Rather, the discussion is meant to offer a preliminary sense of the field and its approaches to the intersections of law, politics, society, and space.

Research Directions

A sizable body of scholarship has been devoted to examining how law frames space, that is, how geography is embedded within legal reasoning and how legislatures and courts make (sometimes unconscious) claims about the relationship between people and place when they draft, examine, and overturn laws. At the international scale, this idea is seen in legal struggles to govern trade and human migration into the European Union or at the United States/Mexico border. In such cases, the law is a key forum through which spatial borders, barriers, and limits are both pulled down and reestablished. At finer scales, too, court rulings and legislative texts provide valuable insights into how ideas about community and identity are inscribed in legalized common sense. In the United States, for instance, courts have been called to evaluate the legality of the electoral districts created after each census, leading to often aesthetic judgments about the “natural” shape of communities and the relationship between geography and identity. Like citizenship, community is a profoundly geographical category, one that is often hard to separate from a territorial unit of space. Here, the law is a powerful medium where some claims about what constitutes a community are deemed legitimate while others are not—the sort of judgment that people might well make on a day-to-day basis but that, when legally enshrined, carries numerous implications for political and social life. Other work has sought to analyze laws and legal reasoning relating to the development and restoration of parks, monuments, and other elements of the built environment, tracing the legal landscape often at work within the geographical landscape of the built environment.

Geographers and anthropologists have also scrutinized the lived geographies of law, the ways in which law, geography, and power are experienced in everyday life. Struggles over community-policing tactics and the spatial spread of legal aid clinics and health care services point to how law, space, and power operate within a sociospatial context. Ethnographic accounts of police work chronicle how law enforcement authorities use a series of geographical strategies to police and control the populations under their purview, while

work on gypsies and refugees has sought to map how these populations negotiate their passage from place to place and contend with law enforcement authorities. Also, scholarship addresses the geographies of privacy, wiretapping, and the legal governance of sidewalk spaces, labor strikes, and the like. Here, courts, legislators, and city councils have sought to govern the kinds of privacy and autonomy that should be accorded to people in public spaces, creating a set of geographical claims about where, exactly, the public and the private are found that affect public life and autonomy in important ways.

Finally, research has focused on *geographies of resistance*. In many instances, the spatial consequences of the law have provoked popular movements (strikes, protests, occupation) designed to disrupt its intended application and to highlight the disruptions and violence that take place when the law is used to disrupt or destroy complex patterns of social relations. Resistance to the gentrification of lower-income neighborhoods, for instance, highlights how law in the form of urban planning policy and policing techniques has prompted the creation of social and political movements designed to challenge the spatial strategies of state control to which these communities are often subjected. In this way, the law has emerged as a repressive and controlling force and, in turn, as a site of resistance.

Conclusion

The geography of law offers a rich and complex way of thinking about the relationship between law and space, providing valuable insights into the shifting juridical-spatial parameters of the social, political, and cultural worlds. Ongoing research, in turn, has sought to draw the field of legal geography out of the Anglo-American context and into other national and institutional contexts. Also, increasing attention is being paid to the connections between law, space, and environment, a departure from the traditional focus on law, space, and society.

LEARNING REGIONS

The concept of *learning regions* reflects the rapid economic development in places such as the “Third Italy” (that country’s high-technology zone centered on Emilia-Romagna), which drew attention to the importance of cooperation between small- and medium-sized establishments (SMEs) in industrial districts and between firms and local authorities at the regional level in achieving international competitiveness. Theoretically, the idea reflects the view of post-Fordist societies as learning economies, where innovation is seen as a socially and territorially embedded, interactive learning process that cannot be understood independently of its institutional and cultural contexts.

Although these contributions share a common emphasis on the important role of innovation as contextualized social processes of interactive learning, they also disclose interesting differences. One such difference can be identified between the American and European approaches. Learning

regions in a North American context are closely associated with the knowledge infrastructure of leading universities and research institutions, which play an essential role in a knowledge-based economy, producing, attracting, and retaining highly skilled workers (e.g., Silicon Valley). In contrast, the focus of learning regions in a European context is more on the role that social capital and trust play in promoting formal and informal interfirm networks and the process of interactive learning (e.g., the industrial districts in the Third Italy). As the differences in these interpretations of learning regions demonstrate, the concept can be fuzzy, and its use both theoretically and practically is rather flexible. To provide an analytically more precise understanding, the next section of this entry identifies three important building blocks of the concept.

Building Blocks of the Concept of Learning Regions

The concept of *learning regions* has been used in at least three different ways. The notion was originally introduced by economic geographers in the mid 1990s, when they used it to emphasize the role played by cooperation and collective learning in regional clusters and networks to promote the innovativeness and competitiveness of firms and regions. The second approach originates from the writings of evolutionary and institutional economics, where innovation is seen as a socially and territorially embedded, interactive learning process, making knowledge the most fundamental resource and learning the most important process. The third approach, which conceptualizes learning regions as regionally based development coalitions, was developed by organizational researchers taking their knowledge of how to form intrafirm and interfirm learning organizations and applying it at the regional level as a bottom-up, horizontally based cooperation among different actors in a local or regional setting.

When learning regions are defined in this way, they resemble a regional innovation system, incorporating the elements of a bottom-up, interactive innovation model. The innovation system concept can be understood in both narrow and broad ways. A narrow definition of the innovation

system primarily incorporates the research and development (R&D) functions of universities, public and private research institutes, and corporations, reflecting a top-down model of innovation. A broader conception of innovation systems includes all aspects of the economic structure and the organizational and institutional context affecting learning and innovation in a region. This type of regional innovation system may be denoted as a “territorially embedded regional innovation system,” in which firms base their innovation activity mainly on localized learning processes stimulated by geographical, social, and cultural proximity, without much direct interaction with knowledge-creating organizations (i.e., R&D institutes and universities).

Learning and Innovation in Regional Economies

According to the perspective on learning regions as regionally based development coalitions, they should be looked on as a way to formulate long-term, partnership-based development strategies initiating learning-based processes of innovation and change. In the promotion of learning regions, the interlinkages of learning organizations ranging from work organizations inside firms to different actors of the community, or “regional development coalitions,” are highlighted. Of strategic importance in this context is the capacity of people, organizations, networks, and regions to learn. The concept of a learning region can thus be used to describe a region characterized by innovative activity based on localized, interactive learning and cooperation promoted by organizational innovations to exploit learning-based competitiveness. This view implies a broad understanding of a regional innovation system with a strong focus on competence building in addition to learning and innovation. Thus, knowledge and innovation should not simply be equated with R&D. Innovative activities have much broader knowledge bases than just science-based R&D, and there are many examples of nations and regions demonstrating rapid economic growth and a high living standard with an industry competing on the bases of non-R&D-based incremental innovations (e.g., Denmark and the Third Italy).

The attractiveness of the concept of learning regions to planners and politicians lies in its promise of economic growth and job generation as well as social cohesion. As such, learning regions may be analyzed as a response and a challenge at the regional level, especially for regions with weak territorial competence bases, to contemporary changes in the global economy, underlining the strategic role played by social capital's emphasis on the social and cultural aspects of regions facilitating collective action for mutual benefit. Thus, it is not accidental that this approach to learning regions was used by the European Union as part of new policies to promote the less developed regional economies within it.

LEFEBVRE, HENRI (1901–1991)

Most well known to geographers today on account of his elaboration of the spatial character of contemporary capitalism, Henri Lefebvre also has an honored place in what is called *cultural studies* due to the interdisciplinary nature of his writings. Born in Hagetmau in the Pyrenees, Lefebvre became a professor of both philosophy and sociology and ultimately a prominent French intellectual whose life spanned almost the entirety of the 20th century (1901–1991). The expansive character of his life parallels his prolific output as the author of more than 60 books, many of which still await translation from French into English. Although the breadth of topics covered in his works is staggering, two of this self-proclaimed Marxist philosopher's most enduring themes center on everyday life and the production of space.

To understand Lefebvre's life—and his life's work—is to understand the key problems of the 20th century as a whole. Moved by the large and violent struggles that coincided with his early life, namely, World War I and the Russian Revolution, Lefebvre came to be regarded as a lifelong committed activist. He shared ideas with proponents of surrealism and existentialism such as André Breton and Jean-Paul Sartre, and during World War II, he became a resistance fighter in

the south of France. After the war, he worked as a taxi driver in Paris, gaining the significant knowledge of city life that is expressed in his theoretical writings. He cultivated an often turbulent relationship with the French Communist Party from 1928 until his expulsion in 1957, soon afterward publishing an autobiography titled *La somme et le reste* [The sum and the rest] in 1959. His friendship with the Situationists, including Guy Debord, ended in a dispute over the ownership of ideas. Still, Lefebvre was regarded as one of the intellectual godfathers of the upheavals of May 1968, and he published *The Explosion* (1968), a depiction of the events of that year. He also came to heavily denounce the structuralism of Louis Althusser, who reciprocated Lefebvre's feelings of contempt.

Although his life's work is located at the intersections of geography, sociology, literary criticism, and urban studies, Lefebvre initially moved to the Sorbonne in Paris during the 1920s as a student of philosophy. There, he soon formed part of a group of rebellious young philosophers whose chief target of attack was Henri Bergson, a noted philosopher of temporality. Whereas both thinkers were intent on reconciling philosophy with lived experience, in contrast to Bergson, Lefebvre underscored the encounter between philosophy and the ideas of Karl Marx. In *The Survival of Capitalism* (1973), Lefebvre remarks that although Marxian thought is not comprehensive enough on its own, it is "indispensable," as is evidenced by the titles of two of his works that have seen English translation: *Dialectical Materialism* (1939) and *The Sociology of Marx* (1966). It was Marx's notion of alienation that first captured Lefebvre's attention, as demonstrated by his early work titled *La conscience mystifiée* (Mystified Consciousness, 1936, cowritten with Norbert Guterman and still untranslated). This early work on a topic that he believed Marx had not sufficiently explored brought Lefebvre to outline his most extensive and most ambitious project: a critique of "everyday life."

No fewer than three volumes of Lefebvre's *Critique of Everyday Life* were published during his lifetime (1947, 1961, and 1981). In all of them, he considers the topic from a characteristically interdisciplinary approach, continuing to flesh out the Marxist concept of alienation as not only

economic but also social, political, ideological, and philosophical. The subject matter of the three volumes of the *Critique* blends literary and cultural analysis with philosophy and the social, economic, and historical changes of the postwar period. This eclectic approach is continued and even taken to its limits in the posthumously published volume titled *Rhythmanalysis* (1992), a term that Lefebvre attributes to the work of Gaston Bachelard in the second volume of the *Critique*. Partly written in collaboration with his wife, Catherine Régulier, this group of essays has been considered a fourth volume of the *Critique*. In the claim made throughout the essays for a less analytical approach to the rhythms of everyday life, Lefebvre anticipates the attention given to mobility by recent scholarship in geography. His *Critique* directly influenced Michel de Certeau's book *The Practice of Everyday Life* and remains a seminal text in the field of cultural studies as a whole.

Concurrently with the *Critique*, Lefebvre also elaborated on the spatial character of capitalism, giving particular attention to cities and the urban. Critics have often taken the heart of his spatial endeavor to be *The Production of Space* (1974), where he outlines a dialectical understanding of space as shaped and reshaped through representational spaces, spaces of representation, and spatial practices. Ultimately, for Lefebvre, space is crucial not only to capitalism but also to the contestation of capital. In taking on the concept of space, he once again returns to a topic that he states was insufficiently explored by Marx. Nevertheless, his ideas on space and the urban were not always well received, as is evidenced by his conflict with Manuel Castells, his former assistant in Nanterre, France, and author of *The Urban Question*. History, however, has looked favorably on this direction of Lefebvre's work, as can be seen in its revival, particularly in Anglophonic criticism, by geographers such as David Harvey and Edward Soja. Among English language readers, one of his most widely read pieces on urban space is "The Right to the City" (1968), which continues to be an important work for geographers, among them Don Mitchell, who published a work with the same title in 2003.

In totality, Lefebvre's work is an explicitly political project that reconciles Marx's critique of capital with the textures of everyday life and the

spatial concerns of the geographer. Although studying his life and work may not be enough to understand 20th-century events and thought, it is indispensable.

LEGAL ASPECTS OF GEOSPATIAL INFORMATION

Legal aspects of geospatial information refers to the legal requirements and restrictions governing the use of geographic information, including information generated through geographic information systems (GIS). There are six key legal issues associated with geospatial information:

1. Liability (contract and tort)
2. Public access to, use, and ownership of geoinformation and geographic data

3. Intellectual property rights
4. Copyright
5. Spatial data privacy
6. Evidentiary admissibility of GIS products

Liability

Liability laws apply to organizations that use, sell, or give geographic information as well as to purveyors of GIS software. U.S. courts have held GIS providers liable and determined that they should bear some financial responsibility for damages if their actions result in mistakes that damage or harm others. Evolving case law deals with GIS such as aeronautical and navigational maps, subjecting them to product liability laws. State and local agencies that sell geographic information at a profit most likely face greater liability than agencies that disseminate the information at cost, release information according to Freedom of Information Act (FOIA) rules, or provide data for free.

Public Access and Data Ownership

Property rights are at the heart of issues related to law as these rights are related to the ownership of geographic information. In the case of geographic information, the owner of the data set also owns the copyright to the information; thus, ownership confers exclusivity of use and control of the information. The U.S. federal government cannot legally copyright the data it collects; furthermore, the FOIA requires that data sell for no more than the cost required to reproduce them. In contrast, U.S. state and local governments can legally own data, and some have used the sale of geographic information as a means to generate revenues. Records whose dissemination may pose a threat to national security may be withheld from use outside their originally intended purposes; however, the legal process permits individuals or organizations to petition for the release of withheld information.

Intellectual Property Rights

Intellectual property rights apply to several different fruits of intellectual labor: (a) original works of authorship, (b) functional inventions,

(c) trademarks, and (d) trade secrets. Among these, it is the first, original works of authorship, that is most applicable to GIS. Traditional criminal law related to intellectual property rights is designed to handle rights associated with tangible objects, such as the physical written word; thus, it is ill prepared to address GIS data and information. Today, the World Intellectual Property Organization (WIPO), under the auspices of the United Nations since 1974, is addressing the unique issue of digital intellectual property under its “Digital Agenda.”

Copyright

Copyright is the legal means to protect intellectual property rights of original works of authorship, including GIS data and products. Copyright protection automatically resides in original works of authorship, with no mark or notice required. While publication is not a prerequisite for copyright protection, copyrighted work must be in a tangible and identifiable physical form. Paper maps were first covered by copyright protection as pieces of literature or art, under the Berne Convention of 1886. Today, digital mapping media and GIS data sets and software also meet this standard. In the United States, a copyright is valid as long as its last author survives and remains valid for an additional 70 years. The copyright on a work “made for hire” lasts for 75 years from its date of publication or for 100 years from the date it was created, whichever comes first.

Privacy and Confidentiality

Data privacy and confidentiality are growing in importance in the GIS communities. The ability of GIS to combine previously unrelated databases with specific locational information provides improved means for tracking the whereabouts of individuals. Concerns about privacy and confidentiality stress the dangers of government-held data, citing Orwellian “big brother” scenarios. The ability to match and integrate separate and disparate digital databases collected by government poses a threat to our privacy, especially when they can be integrated with and augmented by private data sets, such as those owned by insurance companies or credit-reporting bureaus, in a for-profit setting.

Law regarding data privacy appears to be trending toward diminution of privacy rights. Generally, legal decisions regarding Fourth Amendment protections against unreasonable search and seizure have held that there is a difference between what occurs inside our homes (where we may expect protection of our privacy) and what occurs in public space. Codes of ethics represent an extra-legal safeguard for data privacy; however, they do not have the weight of law.

Evidentiary Admissibility of GIS Products

One last issue is how GIS products fare as evidence in courts of law. Evidence is material offered in a court of law to persuade a jury about the truth or falsity of a disputed fact. All federal courts in the United States abide by the rules of evidentiary admissibility published in the *Federal Rules of Evidence*, and states follow similar sets of published rules.

There is a key contradiction in the admissibility of GIS products: On the one hand, if GIS information is considered as purely a representation of facts, then its admissibility is assured; on the other hand, the classification of GIS products as literary or artistic works under copyright laws raises problems. The ease with which digital data may be altered, leaving no evidence of any changes, is another problem.

GIS information easily clears the first evidentiary hurdle—that evidence must be relevant to be deemed admissible; however, because GIS products may be copyrighted as literature or art and thus may be easily altered, GIS evidence is generally treated as “hearsay” and thus is generally not admissible. There are exceptions; for example, when the GIS evidence qualifies as a business record, developed in the course of regular business practice, it may be admissible. GIS evidence may also be treated as an exception to hearsay rules if it is determined to be authentic. To authenticate GIS products, the developer must do the following:

Show the input procedures used to get the data into the computer

Show which tests were used to ensure the accuracy and reliability of both the computer operations and the information that produced the data

Demonstrate that the computer record was generated in the regular course of business and that the business did indeed rely on it

Legal issues in GIS have changed dramatically over the past decade, encompassing a growing number of concerns that are increasing in complexity and interrelatedness. GIS professionals are wise to consult applicable statutes and case law to ensure that their operations comply with all applicable laws.

LEWIS, PEIRCE (1927–)

Peirce Lewis is a noted cultural geographer who has played a key role in developing ways of understanding landscape. Lewis completed his BA (summa cum laude, 1950) in philosophy and history at Albion College. He subsequently earned both his MA (1953) and PhD (1958) in geography from the University of Michigan. After completing a National Science Foundation fellowship at the University of Washington, he joined the faculty in the geography department at Pennsylvania State University (Penn State) in 1958. Over the next 40 years, not only did his name become synonymous with one of the country's leading geography programs, but the quality of his work also cultivated widespread appeal and international recognition. Lewis's 1985 presidential address to the Association of American Geographers ("Beyond Description") articulates his discontent with mere geographic description. His work has consistently probed great depths, always seeking to better understand space, place, and landscape. As a testament to the high quality of his scholarship, he was honored with numerous awards and fellowships, including a Guggenheim (1986) and a Woodrow Wilson (1987) fellowship. Furthermore, as befits a consummate professor, Lewis's career has shown remarkable balance. He has repeatedly been recognized for teaching excellence, including being the recipient of the highly coveted Lindback Award (1981), Penn State's most distinguished teaching award. In 1995, he retired from academia, yet he has continued to build on his impressive career. Following on the heels of the 2003 J. B. Jackson Award for *New Orleans: The Making of an Urban Landscape*, in 2007, the Association of American Geographers bestowed on the former association president (1983) the Lifetime Achievement Award.

For over five decades, Peirce Lewis published a series of seminal works on topics such as the American landscape, the cultural geography of North America, human-environmental interaction, cartographic analysis, geography and children's literature, and regional geomorphology. Yet the one component that stands out is his relentless pursuit of understanding the forces that

shape the landscape. During the earlier stages of his career, Lewis's attention was focused primarily on the natural environment and the principles of geomorphology. One of his most influential mentors, Pierre Dansereau, helped cultivate Lewis's appreciation of changes in the physical landscape. Later, the writings of Carl Sauer, J. B. Jackson, and Henrie Glassey (an American folklorist) became more central to his career, as his professional gaze shifted toward cultural phenomena. Lewis's work has repeatedly stressed the importance of looking for patterns that signal the meanings the landscape holds. No work exemplifies his uncanny ability to interpret the landscape more than his 1979 signature piece, *Axioms for Reading the Landscape*. This publication not only helps readers understand how to appreciate the built environment, but it gives clues to reveal the messages it is sending us.

Lewis's drive for understanding landscape change (both natural and cultural) has remained steadfast throughout his career. Contrary to his unassuming personality, Peirce Lewis's work has inspired and empowered geographers at all stages in their careers. Fledgling graduate students share an equal admiration with seasoned professors for the quality and insightfulness of his publications. Many of today's leading scholars can trace the evolution of their geographic thought back to Peirce Lewis.

LEWIS AND CLARK EXPEDITION

Historical convention of long standing has it that the expedition of Meriwether Lewis and William Clark was dispatched by President Thomas Jefferson in 1804 to explore the newly acquired territory of Louisiana. In fact, the exploration of Louisiana was a secondary part of the mission of Lewis and Clark. Their primary objective, made clear by Jefferson in a number of letters and other documents, was to locate a commercially practical water route across the North American continent. In other words, Lewis and Clark were sent to find the fabled Northwest Passage. That their expedition (1804–1806) coincided with America's acquisition of the vast territory of Louisiana—the entire western portion of the Mississippi's drainage basin—was simply fortuitous (see Figure 1).

By the time Jefferson was elected president in 1800, he had already made three aborted attempts to have some kind of water route between the Mississippi and the Pacific explored. His thinking was simple and consistent with geographical theory of the later Enlightenment: All major rivers had a common source area where their headwaters interlocked. Since a short portage linked the headwaters of the primary eastern branch of the Mississippi (the Ohio) and the headwaters of a major river flowing to the Atlantic (e.g., the Potomac), the Jeffersonian concept of symmetrical geography held that a short portage ought also to link the headwaters of the Mississippi's major western tributary (the Missouri) and a stream, such as the Columbia, flowing to the Pacific. Jefferson impressed on Lewis that his mission had a single overriding objective: to locate this hypothetical short portage between the upper Missouri and upper Columbia, thereby ending a centuries-long search for a water route through or around North America. Jefferson well knew that the country that discovered such a water route would possess enormous commercial advantages, including control over the Indian trade of the interior. To Jefferson, controlling commerce was the most important step to controlling territory, so the mission he set for Lewis and Clark was, first, commercial but with an unwritten imperial objective as well.

Figure 1 A map of Lewis and Clark's track across the western portion of North America, from the Mississippi to the Pacific Ocean

Although Lewis, a long-time family friend of Jefferson's, was selected to lead the expedition, he prevailed on the President to add a co-commander, William Clark, Lewis's former commanding officer in the U.S. Army in Ohio and a close friend. Clark agreed, and after acquiring geographical information from Jefferson's library, learning the rudiments

of scientific observation, and acquiring supplies in Pittsburgh, Lewis traveled down the Ohio River in the summer of 1803, picking up Clark near the falls of the Ohio; the two recruited army and other personnel and went into winter encampment across the Mississippi from St. Louis, at that time the jumping-off point for western travel.

Source: Lewis, S. (Copyist), & Harrison, S. (Engraver). (1814). A map of Lewis and Clarks track. In P. Allen, N. Biddle, W. Clark, & L. Meriwether (Eds.), *History of the expedition under the command of Captains Lewis and Clark*. Washington, DC: Library of Congress, Geography and Maps Division.

After a winter spent preparing their command for an arduous journey, the Lewis and Clark expedition started up the Missouri River on May 14, 1804. Clark's estimates indicate that they planned to reach the Pacific and travel back to St. Louis within one traveling season. This highly inaccurate calculation was, of course, predicated

on the Jeffersonian notion of a short connection between the upper Missouri and the upper Columbia Rivers. By late fall of 1804, the expedition had reached only as far as Central North Dakota. They built Fort Mandan near the Knife River villages of the Mandan and Hidatsa Indians. This area had been, for 1,000 years, the central point

of Indian trade on the upper Missouri and was a well-known location for white traders as well, who had been contacted by French traders out of Canada in the 1730s, and a favored destination for St. Louis traders since the 1770s. Through the first leg of their journey, then, Lewis and Clark were traveling through well-known territory. Beyond the Mandans, all was conjecture. During their winter sojourn with the Mandans and Hidatsas, they learned much of the country to the west, and Clark prepared a map based on information from the Indians. This map—accurate in its basic form but wildly out of scale—showed the source of the Missouri River only about 200 mi. (miles) from the Pacific and just across a final dividing ridge from the Great River of the West, the Columbia. During the summer and fall of 1805, the explorers would learn how inadequately they had been able to convert Indian information on distances and direction into a Euro-American frame of reference.

Leaving the Knife River villages, the expedition traveled up the Missouri River, past the mouth of the Yellowstone, past the Missouri's Great Falls, and thence to the Three Forks of the Missouri, where they took the westernmost branch—the Jefferson River—which was believed to lead to the fabled short portage between Atlantic and Pacific waters. Certainly, the greatest disappointment of the entire expedition came in August 2005, when Lewis crested the Continental Divide at Lemhi Pass in southwestern Montana and, instead of seeing open plains with a huge river flowing toward the Pacific, saw only the immense Bitterroot Mountains, their tops covered with snow. A long and tortuous trek—down to the Salmon River, which was deemed impassable, over Lost Trail Pass to the Bitterroot River and then over the Bitterroot Mountains—brought the expedition again to navigable waters. In September 1805, they reached the Clearwater River, a tributary of the Snake that flows to the Columbia and, thence, to the ocean. Jefferson's short portage had turned into an overland trip of 640 mi. through some of the most difficult terrain in North America. The expedition finally reached the Columbia's estuary in November 1805 and, in December, built their winter encampment—Fort Clatsop—near Pacific shores just south of present-day Astoria, Oregon. Here, they spent a

miserable winter in the cold and damp of the Pacific Northwest.

The return trip, beginning in the spring of 1806, was spent in sorting out some of the puzzles in western geography that still remained: Where was the connecting link between the Missouri and Columbia rivers? Where was the common source area of the western streams? The captains split their command in an attempt to solve these riddles and, in early August 1806, rejoined near the confluence of the Yellowstone and Missouri, reaching St. Louis on September 23, 1806. There, they began the work of compiling the journal notes and maps of their 28-month journey. Clark's final map showed their answers to the remaining puzzles of western geography. But the connecting link still involved a long overland journey of more than 140 mi. and included a difficult mountain crossing between Clark's Fork of the Columbia and the Missouri. And the common-source area that Clark postulated was a pure geographical myth that bedeviled Western cartographers for another four decades. On his final map, Clark showed the sources of the Missouri, Yellowstone, Big Horn, Platte, Arkansas, Rio Grande, Multnomah (a fictitious river based on mistaken impressions of the Willamette), and Snake—all within an area of about 70 mi.². The later explorations of the Rocky Mountain fur traders would, by the 1840s, clear up this massive misconception. In the meantime, it colored Americans' views of the West and shaped the first phases of western exploration by the fur trade between 1807 and 1836.

For all the misconceptions that remained in the final reports of Lewis and Clark, they were the first to have traversed the American West and returned with voluminous reports—not just on mountains and rivers but also on vegetation and soil and wildlife and indigenous peoples. On their information, the first wave of American entrepreneurs entered the West—Manuel Lisa's Missouri Fur Company and John Jacob Astor's American Fur Company. To paraphrase Bernard DeVoto, Lewis and Clark gave the West to the American people, a West with which the mind could deal. Their expedition marked the end of a three-century-long search for a Northwest Passage. But it culminated in data that could be used by real people in settling and using a real area,

and in that sense, the expedition—based on the tenets of Enlightenment science—ultimately became successful in the context of American utilitarianism.

LEY, DAVID (1947–)

David Ley is a well-known humanistic geographer whose research has dealt with several topics, including symbolic landscapes, critiques of structural Marxism, gentrification, immigration, and urban neighborhoods.

After completing a bachelor's degree at Oxford University, Ley crossed the Atlantic Ocean by ship to begin graduate study in geography at the University of Pennsylvania with Peter Gould. Whereas Gould favored quantitative approaches to geographic analysis, Ley found himself leading others on a divergent path of qualitative research. On the forefront of humanist geography, geography that centers on human experience and interpretation, Ley's doctoral dissertation, *The Black Inner City as Frontier Outpost: Images and Behaviour of a Philadelphia Neighbourhood*, was published in 1974 by the Association of American Geographers (AAG) and became a "classic" in geography, celebrated in recollections published 25 years later. The book explores

the racialized microgeographies of daily life in an African American neighborhood in Philadelphia.

By the time he completed his doctoral studies, Ley was offered a job as an assistant professor in Vancouver, Canada, in the department of geography at the University of British Columbia, where he still works today. In the years that followed, Ley worked collaboratively with other social geographers to build humanistic geography. With Jim Duncan, he explored the relationship between landscape, aestheticization, and interpretive frameworks and authored key texts in social geography. *Neighbourhood Organizations and the Welfare State* (published in 1994 with Shlomo Hasson) examined the struggles among inner-city neighborhood groups.

Ley quickly became an active citizen, student, professor, and researcher in Vancouver and began a program of research on the urban and cultural geographies of the city that evolved throughout his career. The focus of Ley's research changed as he studied the shifting cultural and economic forces in the city and suburbs, from the changes bound up in processes of gentrification to the significant demographic shifts driven by international migration to Vancouver in the late 20th century. His 1996 book on gentrification, *The New Middle Class and the Remaking of the Central City*, straddles the subdisciplines of urban and social geography, tracks the changing demographics in six Canadian cities as greater numbers of women enter the work force, and "follows the hippies" who search for particular urban lifestyles and landscapes. Ley's most recent book, *Millionaire Migrants: Trans-Pacific Life Lines*, examines transnational linkages among wealthy migrants in Vancouver, Toronto, and East Asia.

Ley published many key papers in the fields of urban and social geography and later in the field of migration as he charted population change through immigration and mapped poverty in Canadian cities. An oft-cited paper, "Between Europe and Asia: The Case of the Missing Sequoias," combines his interest in social and urban geography and migration with a close reading of a community struggle over zoning that brings to the forefront the classed, racialized, and cultural dimensions of neighborhood conflict.

Ley was the first codirector of the Vancouver Centre of the Canadian Metropolis Project, one

node in a larger global network designed to fuel research on immigration through collaboration between scholars, policymakers, and immigration service providers. Ley is a fellow of the Royal Society and holds a Canada Research Chair in geography. He became a Pierre Trudeau Fellow in 2003 and was given the Lifetime Achievement Award by the AAG in 2009, to name but a few of the many honors he achieved during the course of his career. Ley trained many geographers who themselves now teach at universities in Canada, the United States, Australia, and Britain.

LiDAR AND AIRBORNE LASER SCANNING

Light detection and ranging (LiDAR), also known as airborne laser scanning, is an active remote sensing technology that measures distances between the sensor and points on the surface and stores the geographic location of those ground points.

Measurement Method

LiDAR systems use pulses of light amplified by stimulated emission of radiation (laser). The time that lapses between emitting a laser pulse, the reflection of the pulse off of a surface, and its subsequent return to the sensor is used to determine the distance to the surface from the sensor in the equation: Distance = (Rate × Time)/2, where Rate is equal to the speed of light and Time is the aforementioned lapse of time for a pulse to return to the sensor. A global positioning system (GPS) and an inertial measurement unit are used to measure the position of the sensor and attitude (angle) of the aircraft. The position and angle of the aircraft are in turn used with the distance measurement to geographically reference the points where laser pulses reflected off of a surface.

Characteristics of LiDAR Sensors

Features of LiDAR sensor systems that may vary include the platform used to carry the sensor, the wavelength of light used for the lasers, whether pulses are discrete or continuous, and scanning characteristics. Most platforms that carry LiDAR systems are either small manned airplanes or helicopters. Some systems are suitable for satellite deployment. Fields such as forestry and surveying use LiDAR technology packaged for in situ, ground-based measurements.

LiDAR sensors often use near-infrared light because it reflects well off of vegetation, in particular, and also strongly off of human-made and other surfaces. Often, LiDAR data are separated into ground and vegetation canopy returns during postprocessing of the data. Applications such as coastal mapping use infrared lasers (which reflect off of the water surface) and green lasers

(which travel through water to an extent) in combination to map shallow areas.

Discrete-return LiDAR uses short laser pulses to collect surface information. One pulse may strike multiple surfaces, and each surface it strikes could reflect back a portion of the emitted energy. A *multiple-return LiDAR* system measures the multiple moments of reflection in the path of one laser, as opposed to recording only the last return. *Continuous LiDAR* measures the full waveform of each laser pulse by continuously recording the intensity of reflection during the laser's travel.

Profiling LiDAR sends a pulse down at nadir to provide a linear trace, or profile, of surface elevation data. *Scanning LiDAR* consists of optics to allow the angle of the pulse exiting the sensor to change, and as the system scans back and forth, the specific angle of the pulse is used in combination with distance, GPS, and inertial measurements to determine the coordinates of the surface reflection point. The frequency of scanning determines the density of LiDAR return points with respect to the footprint of the laser pulse on the surface. Furthermore, high-angle pulses and topography can affect the quality of a given return.

LIGHTNING

The lightning flash is one of the most visually remarkable, yet scientifically elusive, of all atmospheric phenomena. Though the earliest lightning observations go back thousands of years, perhaps the biggest breakthrough in our understanding of the lightning flash came in the mid 18th century, when Benjamin Franklin suggested—and later proved in his famous kite experiment—that lightning was an electrical phenomenon. Such a discovery set the stage for subsequent research into lightning formation, lightning detection, lightning safety, and even the use of lightning as a source of energy.

To the weather enthusiast, lightning offers incredible visual displays, sometimes referred to as Nature's fireworks. To the scientist, lightning detection provides a wealth of information on atmospheric processes, thunderstorm formation, and interactions between the land surface and the atmosphere, and it can be used to inform forecasters and hazard mitigation specialists. Unfortunately, lightning is also a deadly phenomenon and can cause severe damage to built structures, trees, and airplanes, as well as disrupt power grids and ignite fires.

Lightning Formation

Cloud Electrification

An understanding of lightning formation begins with an understanding of electrical charge in the atmosphere. In the absence of clouds and major weather systems (i.e., “fair-weather” conditions), Earth's atmosphere contains a preponderance of positively charged ions (an ion is simply a charged particle), while Earth's surface contains a preponderance of negatively charged ions. This global-scale distribution of charge is largely the result of thunderstorms, which act to remove negative charge from the atmosphere and deposit it on Earth's surface. Since air is a poor conductor of electricity, an exceptionally large electrical field must be established for lightning to occur. Under fair-weather conditions, Earth's electrical field is relatively weak, but in a thunderstorm environment, the strength of the electrical field increases

Time-lapse photography captures cloud-to-ground lightning during a nighttime thunderstorm in Norman, Oklahoma.

Source: National Oceanic and Atmospheric Administration.

by many orders of magnitude until an electrical current can move freely between the cloud and another conducting surface.

The most popular theory for the development of electrical charge in thunderstorms is the noninductive charging mechanism. Since thunderstorms grow to altitudes where temperatures are below freezing, they become composed of liquid water, ice crystals, and hailstones. Each of these particles has a slightly different arrangement of electrons, meaning that as they collide with each other in the turbulent air currents found within a thunderstorm, electrons will be transferred between them. This transfer of electrons results in an accumulation of positive charge near the upper portions of the thunderstorm (where ice particles are kept aloft) and an accumulation of negative charge in the middle and lower portions of the thunderstorm (where small, but heavier hailstones settle). Secondary charging mechanisms help strengthen the electrical field as electrons are continuously transferred between colliding thunderstorm particles. On the ground, an accumulation of positive charge builds as negative charge near the lower portion of the thunderstorm repels the negative

charge on Earth's surface that existed under fair-weather conditions. When a lightning flash occurs between the cloud and the ground, negative charge is transferred back to the ground.

Lightning Flashes

There are three primary types of lightning flashes: those that occur within the cloud (i.e., intracloud), between clouds (i.e., cloud to cloud), and between the cloud and the ground (i.e., cloud to ground). Approximately 80% of all lightning flashes occur either within the cloud or between clouds. Other types of optical and electromagnetic phenomena, both on the ground (e.g., St. Elmo's Fire) and in the upper atmosphere (e.g., sprites and jets), have been observed in association with lightning flashes.

To the naked eye, a lightning flash appears as a continuous flash of light. However, high-speed photography and laboratory experiments have revealed that a single lightning flash is actually composed of a series of flashes each lasting just a few millionths of a second. In a typical cloud-to-ground flash, negative ions (electrons) begin

moving downward through the cloud toward the ground. To facilitate this process, electrons may branch out and take multiple paths downward—this creates the “forked” appearance of many lightning flashes. As the flow of electrons moves downward, a stepped leader is formed that attempts to establish a conductive channel for electrons to flow through and neutralize the charge difference between the cloud and the ground. As the channel nears the ground, a spark occurs on a conducting surface (e.g., the top of a tree), creating a conduit for electrons to flow through. Once the lightning channel is established, the current flows upward toward the cloud, creating a brilliant flash known as a *return stroke*. Depending on the strength of the electrical field, multiple return strokes may occur in an effort to dispel the negative charge from the cloud.

A less frequent type of cloud-to-ground flash is the positive flash, which transfers positive charge from the cloud to the ground. These flashes often originate in thunderstorms that are horizontally tilted, exposing the positively charged upper regions of the cloud to the ground. Positive flashes may also emanate from the sides of the cloud, striking the ground a considerable distance from the main body of the thunderstorm. This type of flash is often referred to as a “bolt from the blue,” since it occurs away from the thunderstorm under generally clear skies.

Lightning Detection

Prior to the advent of modern lightning detection equipment, the occurrence of lightning was typically inferred by the sound of thunder—the sound wave produced by a lightning flash as it rapidly heats and expands the air around it. Weather observers would mark the presence of thunderstorms in their logbooks if audible thunder was detected. The first attempts to measure the electrical field in the vicinity of thunderstorms took place in the early 1950s and used sferics, or radio waves, to measure electromagnetic radiation produced by the lightning flash.

One of the biggest shortcomings of early lightning detection methods was that they could not pinpoint the true location of the lightning channel. This changed in the 1970s with the development of magnetic direction finders. These ground-based instruments are able to “sense” the

radiation emitted during the first few microseconds when a flash strikes the ground or a ground-based object. The first sensors became operational in 1979 and covered only small portions of the United States. In 1989, these regional networks merged into the present-day National Lightning Detection Network, based in Tucson, Arizona. This network consists of more than 100 sensors that record the time and location of all cloud-to-ground flashes, as well as other characteristics (e.g., magnitude of the electrical current, number of return strokes). Some regional lightning networks in the private sector continue to operate their own direction finders for specialized research and monitoring purposes. Lightning sensors have also been placed aboard satellites to provide global coverage of cloud-to-ground and intra-cloud lightning (a map produced by the National Atmospheric and Space Administration [NASA] showing the global distribution of lightning flashes can be found at <http://virtualskies.arc.nasa.gov/research/tutorial/lightningMap.html>).

Lightning Impacts

Lightning is the leading cause of thunderstorm-related fatalities in the United States, killing an average of 100 people annually from 1959 to 2006. Since the 1930s, lightning fatalities and fatality rates have steadily declined due to a decreasing rural population, improvements in forecasts and warnings, better medical response to victims, and mitigation efforts through public education. Fatality rates are often much higher in less developed countries (6 fatalities per million population) in comparison with more developed nations (from 0.1 to 1 per million). People engaged in outdoor recreational or work-related activities are the most vulnerable to the hazard. Uniquely, males are far more likely to be killed by lightning than females, with males comprising nearly 85% of lightning fatalities in the United States. Victims struck directly or indirectly by lightning often suffer from injuries to the cardiac and neurological systems (cardiac arrest being the most common cause of death) as well as psychological effects that include neurocognitive deficits, memory problems, and even depression. The spatial distribution of lightning fatalities and injuries is commensurate with population and cloud-to-ground lightning densities. Casualties tend to occur most

often during warm-season afternoons, when thunderstorms are at their climatological maximum and people are more likely to be outdoors.

Lightning routinely causes damage to personal, commercial, and public property and is a major source of property, agricultural, and casualty insurance losses. Though lightning losses are often isolated and rarely achieve the tallies reported for other weather hazards such as tornadoes and hurricanes, the cumulative insured losses from lightning are considerable, with an estimated \$5 billion in insured losses annually. Lightning regularly disrupts electricity generation, transmission, and distribution. The hazard is a major cause of local and regional electrical and telecommunication blackouts and inflicts losses of millions of dollars annually on utility infrastructure and sales. Lightning-initiated wildland fires result in annual timber and property losses of millions of dollars, with millions of dollars more spent on fire prevention and suppression in the more developed countries. The National Interagency Fire Center estimates that approximately 12,000 wildland fires are initiated by lightning each year in the United States, affecting an average of 5 million acres annually.

Geographical Studies of Lightning

The spatial and temporal distribution of lightning flashes and the utility of lightning data sets have been explored in a variety of geographical studies. The general goal of these studies is to inform researchers and those with lightning-oriented interests of the patterns of lightning within a range of meteorological and hazard scenarios. Geographers are in a unique position to provide this information using advanced visualization and mapping techniques (i.e., geographic information systems, or GIS) that allow inferences into mechanism, causation, and other process-based inquiries.

The spectrum of geographically based lightning studies is rather broad and contains many overlapping categories and components. Most of these studies employ a descriptive approach, where patterns in lightning frequency are mapped and explained across various space and timescales (i.e., a lightning climatology). Some studies use this information to explore the possible mechanisms for the resulting distributions and the

processes and weather systems that drive them. Still other studies use lightning data to explore various properties of the atmosphere. Improvements in the spatial and temporal resolution of lightning data have allowed for such investigations from the macroscale down to the microscale. Examples include the use of lightning data to understand the role of aerosols and other small particles in thunderstorm composition, rainfall, and cloud electrification as well as the atmospheric processes occurring in severe thunderstorms, tropical cyclones, and winter storms (e.g., “thundersnow”). Lightning data have been used in macroscale studies to examine the relationship between atmospheric circulation patterns and the frequency and intensity of convection in subtropical and midlatitude environments.

Among geographers who use lightning data sets, the role of land use in initiating and altering the frequency and character of lightning flashes has been a popular research topic in recent years. In particular, there has been a significant growth in the number and scope of studies examining the lightning climatology of urban areas, both in the United States and abroad (e.g., South America, Western Europe, Australia). These studies are part of a much larger initiative aimed at examining how the urban environment affects atmospheric processes across multiple scales. Relatively fewer studies have investigated the distribution of lightning over mountainous terrain and the relationships between slope angle, aspect, elevation, and lightning frequency. Continued improvements in lightning detection networks and a longer time series will likely lead to more studies of lightning over complex terrain. Additionally, the continued development of satellite-based lightning sensors will provide a longer time series of lightning coverage over the oceans and higher latitudes. This information will be of value to studies examining the global distribution of lightning and its trends over time, particularly in the context of global and regional climate change. Continued development of GIS technologies will be of tremendous benefit to climatological studies of lightning as well as studies exploring the relationships between lightning and other aspects of the Earth system (e.g., land cover, demographics) across space and time.

LILLESAND, THOMAS (1946–)

Thomas M. Lillesand has long been a major figure in the development of remote sensing techniques, applications, and policies. He is a professor emeritus of the Nelson Institute for Environmental Studies, the department of forest ecology and management, and the department of civil and environmental engineering at the University of Wisconsin, Madison (UW).

Lillesand grew up in Wisconsin and obtained degrees in civil engineering from the UW (BS, 1969; MS, 1970; PhD, 1973). He began his career as a remote sensing educator in 1973, as a faculty member at the State University of New York (SUNY), Syracuse, College of Environmental Science and Forestry. From 1978 to 1982, he taught at the University of Minnesota and directed that university's Remote Sensing Laboratory. He joined the faculty at UW in 1982 and was the

director of Wisconsin's Environmental Remote Sensing Center (ERSC). For many years he also chaired UW's Environmental Monitoring graduate program.

Lillesand taught numerous courses in photogrammetry, visual image interpretation, photographic and electro-optical remote sensing systems, digital image processing, environmental monitoring, and graduate research methods. He advised a total of 76 MS and PhD students over the course of his academic career. Many of these have become leaders in key positions in academia, government, and the private sector. The scope of Tom's highly interdisciplinary research activity has ranged from statewide and regional land cover classification and change detection to applications of remote sensing in forestry and agriculture, civil engineering, long-term ecosystem science, climate change, and water resources management. Sponsors of his research have included the National Atmospheric and Space Administration (NASA), the National Atmospheric and Oceanic Administration (NOAA), the U.S. Department of Agriculture (USDA), the National Science Foundation (NSF), the U.S. Army Corps of Engineers (USACE), the U.S. Geological Survey (USGS), the Department of Energy (DOE), and the Environmental Protection Agency (EPA), among others. He has also been active in U.S. remote sensing policy issues.

Lillesand has authored or coauthored more than 200 professional publications. He is the senior author, along with Ralph Kiefer and Jonathan Chipman, of *Remote Sensing and Image Interpretation*, published in 1979 and now in its sixth edition. This book has been translated into several languages, making it one of the most used remote sensing texts and references in the world.

Over the years, Lillesand has provided frequent service as a consultant and scientific advisor to numerous governmental agencies, as an expert witness, and as a leader in professional organizations. For example, he served on the Science Advisory Panel for the Earth Observing System (EOS) Land Processes Distributed Active Archive Center. He was appointed by Secretary of Commerce Malcolm Baldrige to represent the American Society for Photogrammetry and Remote Sensing (ASPRS) on the Land Remote Sensing Satellite Advisory Committee and has provided both U.S.

House and Senate subcommittee testimony on four occasions dealing with the policy and management of the U.S. Landsat satellite program and defining the basic research requirements underpinning U.S. commercial opportunities in geospatial science and technology. Lillesand has also chaired and served on numerous key committees for ASPRS. He has served as an officer within three ASPRS Regions and as director of the Remote Sensing Applications Division. He served as the national president of ASPRS from 1998 to 1999. He has received several national awards for his professional accomplishments, including the Alan Gordon Memorial Award for Scientific Achievements in Remote Sensing and Image Interpretation, the Talbert Abrams Award for excellence in Authorship and Recording of Scientific Development in Photogrammetry, the Earle J. Fennell Award for Outstanding Contributions to Education in the Mapping Sciences, and the SAIC/Estes Memorial Teaching Award. He is a fellow in ASPRS, a certified photogrammetrist, and a certified mapping scientist in the area of remote sensing.

Lillesand retired in 2006, after 33 years as a teacher, researcher, and advisor, but continues to serve as president of the Board of Trustees of the ASPRS Foundation. He also consults on a part-time basis, primarily as an expert witness.

LINEAR REFERENCING AND DYNAMIC SEGMENTATION

Dynamic segmentation is a computer-based database management system using the principles of relational algebra and topological integrity to minimize error and maximize efficiency of map analysis and display. Linear features are stored as nodes and arcs and provide only the minimum of geometric properties for proper display on maps.

When these linear features, such as roads and railways, have multiple attribute tables, dynamic segmentation is used to query and display such attributes. Examples include the number of accidents at different parts of the pavement or speed limits that differ within the same segment. Since geometric nodes and arcs are the foundation of linear features stored in a geographic information system (GIS), dynamic segmentation becomes quite useful to represent attribute data that do not sync perfectly with the geometric range of the linear features.

Utilities and transportation networks often have information without geographic coordinates. Usually, this information is based on a fixed reference point along a route. The data stored are referred to as a *linear referencing system*. For example, highway accidents often are coded based on the nearest intersection and the network distance from the intersection (i.e., the driving distance from the accident location to the nearest intersection). Tables containing such information are known as *milepost tables*. Using a map, one can dynamically calculate the coordinate information and display accident sites. Since dynamic calculations can be done using computer memory, the storage of such information permanently is deemed redundant. In addition, since highway maps and other linear maps are stored and updated independently of the accident tables, there is no need to separately change the accident coordinates whenever a highway map is updated (since, in the milepost table, there are no accident coordinates to begin with). This approach restricts the propagation of error and is important since geometric coordinate error cannot be eliminated. Another benefit is that line segments need not be broken into smaller pieces. Actual breaks are limited to intersections with other lines or change of direction in the line segment.

Logical Data Model

Network data, which are used extensively in the transportation and utility domains, have benefited immensely from graph theory—a branch of mathematics that studies the properties of nodes and arcs. A graph, $G = (V, E)$, consists of a finite set of vertices, V , and edges, E (joining the V s). When the edges are directed and the vertices are weighted, they represent a network. The geometric coordinates of the vertices allow the network to be mapped in relation to Earth's surface. However, the properties of the network are independent of the actual coordinates and are a function of the number of edges the vertices enclose (the mathematical branch of low-dimensional topology deals with the properties of graphs).

Milepost tables use this topological property of the network, allowing storage of complete information without map duplication.

GIS software that incorporates dynamic segmentation includes Environmental Systems Research Institute's ArcGIS software and Caliper Corporation's TransCAD software.

LITERATURE, GEOGRAPHY AND

The study of literature from a geographical perspective takes as its premise the recognition that questions of space, place, and spatiality are constitutive of, rather than merely supplementary to, the kinds of meaning, significance, and communication that literature produces. This idea exceeds the simple recognition that literary narratives

(poems, novels, myths, etc.) unfold at particular locations. Rather, there are five broad fields of literary geographical concern:

1. Literature as a humanistic and meaningful narrative of place
2. Literature as an object of historical geographical analysis
3. Literature as a site of ideological critique
4. Literature as an exposition of postcolonial geographical imaginations
5. Literature as an expression of particular spatialities and their attendant "structures of feeling"

Within these fields, the relation between text and context is taken seriously, because it is in this site that the historical, social, political, and philosophical significance of literature is most acute—precisely because the geographical and historical contexts of literary production and consumption affect and determine that significance.

As Andrew Thacker has noted, literary texts represent social spaces. For example, from the enclosed, gendered spatialities and formal social marriage circuits of Jane Austen's predominantly rural England to the modernist urban encounters and fragmentary perspectives of James Joyce's Dublin, literature inscribes a whole history of sociospatial relations and images of geographical reality. At the same time, social spaces shape literary forms. Thus, there are particular spatial histories to writing communities and their readerships, in which social, economic, and political contextual relations feed into the production of distinct literary forms. Geography shapes literary history, as literatures are both expressions of particular cultures, nationalities, and languages and at the same time sites of passage, translation, and communication between different cultures, identities, and beliefs.

Geography has also fed into the study of narrative (diegetics) within literary criticism. Since the "spatial turn," literary studies often employ spatial languages and metaphors to better explicate the ways in which narrative functions and has its own "textual space," extending from the materiality and locational specificity of the book to the structured space of the page itself. Spatial metaphors have thus become ubiquitous within literary

criticism. Border, boundary, margin, orientation, mapping, (de)territorialization, and so on have come to be constitutive of literary sense.

Humanistic Geography: Narratives of Place

The first sustained geographical engagement with literature was through humanistic geographers of the 1970s and 1980s such as Yi-Fu Tuan, Douglas Pocock, and Anne Buttimer. They sought to study literature as a way of thinking about the more subjective ways in which people experience particular places and render them meaningful. In reaction to the dominance of quantitative methods of sociospatial analysis, particular novelists and literary representations of places were studied from a nonmathematical horizon of meaning, memory, and identity. Humanistic research on a given author or novel would, on the one hand, seek to communicate how literature carried a sense of “authentic” geographical awareness of the lives, worldviews, and practices associated with a specific milieu or a particular place. On the other hand, and reflecting perhaps a naive acceptance of literature as a taken-for-granted creation of artistic “genius,” it would also claim for literature universal capacities for the illumination of humanity not found in social scientific research. This approach can be traced historically to J. K. Wright’s 1947 presidential address to the Association of American Geographers, “*Terrae Incognitae: The Place of the Imagination in Geography*,” in which he called for greater geographical engagement with literary criticism and the humanities more broadly.

For Marxist geographers, however, humanistic geography, focusing primarily on “the text” and the privileged insight that an authorial voice lends, lacked the requisite level of criticality. Beyond the cultural turn, this criticality in relation to literature can be seen in the three subsequent fields of research, encompassing questions of textuality, the historicity of literary texts, and the politics of representation more broadly.

The Object of Historical-Geographical Literary Analysis

In explicating the geographic work of literature, historical geographers seek to unpack texts in

relation not only to the historically distinctive representations of fictional and “real” space (actual or imagined landscapes, nations, cities, ruralities, etc.) but also to the spatial contexts that condition the production and consumption of an object named *literature*. In this way, geographical literary study does not provide access to “language” in a pure form but to writings in the plural, in their varied geographical and historical specificity. Literature, in the widest possible sense, involves the production, dissemination, and consumption of novels, stories, tales, and myths of whatever genre (picaresque, religious-moralistic, colonial, gothic, crime, avant-garde, romance, etc.). Within this context, literature arises as an aesthetic category, defined through complex social assemblages: authors, editors, publishers, technologies of paper and ink, reviewers, critics, and historians. However, beyond the scope of particular scholarly aesthetic definitions of literature, there is also the more banal, but no less important, everyday production of literature found in the writing of letters, e-mails, Internet blogs, diaries, and so on. Different print cultures can be geographically examined as the contested and evolving locus through which positions such as “author” and “reader” come to be articulated.

Focusing on a particular literary form, critics such as Franco Moretti and Pierre Bourdieu describe the spatial histories of the novel. The novel form developed primarily in the 18th- and 19th-century European contexts, where industrialization, the development of the bourgeoisie, the rise of nation-states, and imperialistic and colonial encounters unfolded within the wide economic and social transformations of urban capitals such as Paris and London. While these cities exerted a hegemonic publication and print culture, conditioning practices of reading and expectations (literary canons and genres, library stocks), literature is not thereby tied in any concrete and definitive way to its sites of origin. Literature travels; texts are translated, styles imitated, and ideas disseminated. Books are thus mobile commodities that trace out important social lives.

Literature as a Site of Ideological Critique

As commodities, the consumption of literature can be analyzed as part of the uneven distribution of

cultural capital more broadly. For Bourdieu, this ideological class stratification is historically and geographically produced. In this way, the aesthetic appreciation of the *form* of literature is scripted along particular class boundaries and types of education. Furthermore, many geographers have turned to the specific *content* of literatures, critiquing particular representations and imaginations that are culturally repressive, ideologically hegemonic, and normalizing. For these geographers, literature figures as a crucial site for the (re)production of particular geographical ideas, consciousnesses, identities, and cultures (nationalities, races, classes, genders, etc.). Literature can thus be framed as a conservative site for the reproduction of particular values. But, for the same reason, it can carry a transgressive function of resistance, critique, and democratic expression.

With critical resources from the “cultural turn” (the widespread acknowledgment of the centrality of culture and ideology in all social systems), geographers study how particular geographical imaginations are disseminated, reproduced, and framed through certain types of language, form, narrative, and style. By unpacking the work of narrative and employing concepts from literary theory, geographers can grasp the structured ways in which meaning is articulated through habitual media forms. Thus, certain forms of textual representation perform particular relations of power, from popular novels to mundane nonfiction texts, including the encyclopedic entry, which replicates a specifically structured narrative space to communicate authoritatively. In this way, it is important to unpack the complex and ambiguous relation between truth and fiction that literature inevitably throws up. Spaces, places, and particular geographic communities (classes, cultures, nationalities, genders, races, historical events, etc.) are framed through literature. Texts often (problematically) reduce social geographical complexity within narratives. These representations inevitably run up against notions of truth: the accuracy of representation, the level of their reality. They also come up against their opposite: where a text is dismissed as “purely fictional,” as that which is merely imagined and desired. In reality, it is incredibly difficult to separate these, and a critical geographic perspective is attentive

to how the separation between truth and fiction is enacted or dissimulated and with what particular ideological effects.

The Exposition of Postcolonial Geographical Imaginations

Perhaps the most important field for ideological critique is circumscribed by the postcolonial critic Edward Said. As Said noted, literature is not a neutral aesthetic phenomenon but a site where politics, language, geography, and culture are inextricable, where different geographical imaginations and ideologies are historically produced, reproduced, and contested. Greek dramas and myths, travel writings, colonial novels of romance and exploration—all have historically shaped the ways in which different cultures and places are rendered visible, encountered and imagined, desired and feared. Said coined the term *Orientalism* to describe Western literary practices of constructing and relating to cultural Others, in particular the imagined space of the Orient. Many geographers, such as Derek Gregory, have taken Said’s key literary-historical texts and work to expose the continuing legacies of Orientalist representations within contemporary media forms.

In relation to the historical-geographical analysis of key texts, Daniel Defoe’s *Robinson Crusoe* (1719) and Joseph Conrad’s *Heart of Darkness* (1899) have proved exceptional resources for geographers interested in the geographical history and desires of nation building, the formation of Empire, and the imperialistic practices, moralities, and racisms that are bound up with particular geographical imaginations. An example is the prevalent geographical binary found in numerous literatures of the “Dark Continent” of Africa, contrasted and constituted in relation to the “light” of European civilization, reason, religion, and industry. More broadly, this field is interested in raising questions on the politics of representing and speaking “for” other cultures through dominant colonial languages and literatures (e.g., English and French).

Expressions of Spatiality

As Raymond Williams noted, it is possible to analyze distinct “structures of feeling” attendant on

Chromolithograph of a cooking scene from *Robinson Crusoe*, showing a man dressed in furs cooking meat over a fire while a native carries supplies

Source: Bettmann/CORBIS.

varying historico-geographical experiences of the city, “nature,” the country, and other spaces. These structures of feeling correspond to different spatialities, shaped and experienced in important ways by different kinds of literary representation (poems, novels, religious texts, etc.). Spatiality here can be thought as the co-constitutive relations between society and space. As both society and space are constantly shifting and rewriting their coordinates, different literatures emerge that register particular historico-geographical spatialities. In this context, David Harvey has produced a particularly clear geographical analysis of the works of Honoré de Balzac—situating his literature within the shifting spatialities of the urban, capitalistic experience in 19th-century

Paris. Literature here acts as an important registration of the everyday practices, beliefs, and identities that accompany the broader shifts of historical-geographical materialism. The cultural critic Walter Benjamin provided further theoretical rigor for geographers seeking to make sense of these relations between literature and the spaces of modernity, particularly Paris. Within this horizon, James Joyce is another author whose texts, particularly *Ulysses*, have proved particularly fruitful in explicating the nature of modernist renderings of urban experience and the significance of geographical imaginations in the construction of narratives. Indeed, it was hoped by Joyce that one could reconstruct the city of Dublin from *Ulysses*. What these works signify is the pedagogic value of literature for grasping geographical configurations, consciousness, and the changing horizons of perception of space and time.

LIVINGSTONE, DAVID (1953–)

The history of geography was in some ways rewritten in David N. Livingstone's influential volume *The Geographical Tradition* (1992), which constituted both an important new disciplinary history and an attempt to write geography's history *differently*. Setting his work apart from textbook accounts and "in-house" disciplinary histories, Livingstone's book related the development of geography more closely to its broader social and intellectual contexts than had previous works, from Enlightenment challenges to classical authority, to the colonially acquisitive age of reconnaissance, to the age of statistics and the modern government and academic institutions of the late 20th century. Drawing on wider debates in the history of science, Livingstone demonstrated that geographical knowledge could be understood as a cultural product of, and political resource for, the times and places in which it was produced. He thus took up key questions raised in the post-modern turn in the history and philosophy of science—revolving around the demythologization of science as the objective, disinterested pursuit of knowledge—and explored their implications for the "messy" and applied contexts associated with the Western geographical tradition.

Built on theoretically informed and rigorous historical scholarship, Livingstone's work helped open geography's history to more reflexive and, at times, critical interpretations, and it did so by adding to, rather than detracting from, the historical richness of the field. Livingstone brought to these questions analytical skills honed in unraveling the complex interrelations of 19th-century science and religion. In works such as *Darwin's Forgotten Defenders* (1987), which focuses on some 19th-century theologians, and *The Preadamite Theory and the Marriage of Science and Religion* (1992), Livingstone challenged the "conflict model" of relations between science and religion, incorporating a broad sense of the intellectual diversity present in strains of Christian and evolutionary thought. In the North American context, Livingstone also contributed a major scientific biography of the Harvard physiographer Nathaniel Southgate Shaler. This work (1987) explores the interplay of regionalism,

race, class, and science that shaped Shaler's late-19th-century career and offers, through Shaler, a vital portrait of the Cambridge scientific community during the 1870s and 1880s, when Darwinism shook the intellectual landscape.

Livingstone's close attention to historical context has been matched by a concern for situating scientific actors in their spatial and geographical settings. In a series of papers during the 1990s, Livingstone pushed geographers and historians to consider how particular geographical arrangements of scientific knowledge and knowledge-making practices were critical to what science is and how it has worked. Whether conceptualized in terms of specialized architectural spaces, the research field, or other local settings for scientific activities, in terms of national scientific cultures and institutions and varied national receptions of scientific ideas, or through the spatial relations and patterns of circulation that make such scientific spaces possible, notions of a *geography of science*, and the *geography of geographical knowledge* in particular, have emerged as cutting-edge fields, at both the subdisciplinary and the interdisciplinary levels. Livingstone elaborated some of these ideas in a slim volume, *Putting Science in Its Place* (2003), an elegant formulation of the geography of scientific knowledge as framed by three spatial categories: (1) *sites* (archetypal sites, venues of science), (2) *regions* (regional differences in scientific culture, uneven development of science), and (3) *circulation* (movement, mapping, scientific travel, spatial relations, diffusion). Bringing together scholarship in the history of science with the history and geography of geographical knowledge, Livingstone has also edited, with Charles Withers, recent collections such as *Geography and Enlightenment* and *Geography and Revolution*.

David Livingstone is a professor of geography and intellectual history at Queen's University Belfast, where he earned his PhD in 1982. His honors include the Order of the British Empire for service in geography and history, membership in the Royal Irish Academy, and a fellowship in the British Academy.

LOCALITY

Although human geographers sometimes disagree over the specific meaning of concepts such as place, space, region, and territory, few would question the centrality of such concepts to the discipline. Not so with the concept of locality, which is commonly taken to mean a distinct place or location in which events occur. This concept gained a certain

currency in the 1980s and early 1990s but very quickly became embroiled in a wider debate about theory and methods in human geography. Concerns were expressed by some radical geographers that the study of locality equated with empiricism: It seemed to signal a retreat from geographic theories grounded in Karl Marx's historical materialism. Although proponents of the locality concept vigorously countered such criticisms, they could not fully dispel the view that a fascination with locality amounted to an empiricist obsession with the detailed characteristics of specific places rather than with interrogating wider theoretical propositions about the capitalist space economy.

The appearance of the concept of locality in human geography texts in the mid 1980s can be attributed to an interdisciplinary research program funded by the Economic and Social Research Council in the United Kingdom. The Changing Urban and Regional System (CURS) program was designed with broadly three aims in mind:

1. To conduct detailed empirical research of economic, social, and political change in a variety of localities across the United Kingdom: The localities (seven in all) were selected on the basis of the uniqueness of certain characteristics, such as relative location, labor market, rural/urban mix, size, economy, and politics, as well as the presence of relevant locally based research teams. Although at the outset, there was a clear emphasis on difference and the uniqueness of each locality, the research teams nonetheless shared in common a broader appreciation of the importance of theory and conceptualization.

2. To interrogate wider propositions about the restructuring of the British space economy at a time of rapid economic, social, and political change: The research teams were eager to test certain theories about spatial restructuring that had emerged in the 1960s and 1970s, such as the approach to uneven development set out by Doreen Massey in her analysis of the geography of industrial restructuring. It was argued that locality-specific events and outcomes could not be read directly from global and national processes because “place makes a difference.” This assertion was supported by a definition of locality as those locally emergent properties that result from a putative combination of the particular class and

political relations of a place and wider rounds of investment and economic restructuring.

3. To engage proactively with economic and political change in such a manner as to inform policymakers and activists about the most practical means of contesting and coping with the localized social and economic consequences associated with the transformation of the United Kingdom from a manufacturing to a service economy: A particular target of action here was the neoliberal policies of the Conservative government led by Margaret Thatcher, which were seen by many radical geographers to be blaming the victims of spatial restructuring, that is, workers caught up in the restructuring of industrial localities once heavily dependent on industries such as steel, engineering, automobile manufacture, shipbuilding, and coal. However, the research teams did not confine themselves to male-dominated industrial labor markets; they were also interested in the emergence of new economic forms and the diversity of labor market processes. The teams were especially interested in identifying examples of “proactive localities” or collective action drawing on the resources and civic capacities of the localities in question.

The results of the CURS program were published in a series of journal articles and edited collections, each of which highlighted specific processes such as labor market restructuring, policy and politics, household strategies, and work and everyday life. While some common intellectual themes did emerge, there was little evidence that, collectively, locality studies shared in common praxis and theory; and this was despite the efforts of Doreen Massey and Philip Cooke (the latter was the research program coordinator), both of whom strove to impose some theoretical coherence retrospectively on the locality concept. Indeed, such efforts only intensified criticisms of the project, creating space for some important theoretical contributions from geographers, many of whom were not members of the original locality research teams.

The Significance of Locality Studies

Human geographers eventually moved on from locality studies, with many shunning empirical case

studies to engage in wider epistemological and ontological preoccupations with space and place. Nonetheless, the debate about locality was important for shaping at least two important new developments in the discipline. First, prompted by a memorable analogy from Neil Smith about a hot-air balloon and the “gestalt of scale,” the locality question led to a flurry of theoretical interventions around the production of spatial scale, leading eventually to a “scale debate” in human geography. The question of scale triggered some of the most exciting work to emerge in the discipline in the 1990s and 2000s. Research conducted on scales of labor activism, the rescaling of the state, and the relationship between locality-based growth coalitions and the politics of economic development can be attributed at least in part to the theoretical fallout of the locality debate.

Second, the locality concept engendered some challenging new theoretical work on sociospatial relations. Here, Doreen Massey’s work continues to be influential in its emphasis on the idea that space should not be seen as some sort of residual dimension of social and economic life or as simply a container for other processes that are compositional in structure yet essentially placeless. Rather, space shapes and gives meaning to wider (regional, national, global, etc.) natural and social processes that are, in turn, place shaping.

In hindsight, the appearance of the locality concept marked a tipping point in the transition from territorial to relational views of spatiality, with the latter becoming dominant by the 2000s. However, the debate about locality continues to be relevant, not so much for how it once shed light on local-scale geographies of economic restructuring but rather for what it now reveals about the circumstances under which certain intellectual themes and debates endure in the discipline while others are quickly discarded. Time will tell whether the locality concept will make a return to geography and, if so, in what forms and under what sorts of circumstances. The pendulum of spatial intellectual thought might yet swing back toward locality (as well as to its sister concepts of place, territory, and scale), at the expense of the current interest in globalization (and corresponding ideas of site, relational space, and flat ontology).

LOCALLY UNWANTED LAND USES (LULUs)

The acronym LULU stands for locally unwanted land use—a facility whose siting is resisted by local residents. Typically consisting of hazardous waste repositories, landfills, power plants, highways, and other projects that may pose an environmental or health risk, LULUs may also be prisons, low-income housing, shelters, treatment centers, and other facilities perceived as lowering property values and posing a security risk. A LULU may also be a facility that is resisted due to racial prejudice. LULUs are closely linked to the more common acronym NIMBY (not in my backyard), a term referring to the common position taken by local residents when faced with a LULU.

Geographers and planners take a particular interest in LULUs, because resistance to them illustrates the dynamics of political conflict in urban space. While geographers are more inclined to address the structural conditions giving rise to the LULUs and the NIMBY response, it generally falls to planners to suggest ways to overcome this resistance through measures such as public participation in decision making, risk communication, “fair-share” allocation, mediation, compensation, negotiated settlement, and, when all else fails, outright preemption by higher levels of

government. Justification for public intervention comes through portrayal of local resistance to a public good as parochial and self-serving, typically under the assumption that there is a geographic dichotomy between parochial economic self-interest and regional public goals.

However, beginning in the late 1970s, a critique of this common understanding emerged from environmental and local activists addressing the subset of LULUs involving health threats. They suggested that the term NIMBY presupposed acceptance of the need for the LULU, implying that the facility should be located *somewhere*, just not in “my” backyard, when the facility should be viewed as unacceptable *anywhere*. Such resistance has been particularly noticeable in low-income neighborhoods and communities of color where waste repositories have been proposed. Thus, a more appropriate term for resistance to the LULU in this instance would be NIABY, or not in anybody’s backyard. The latter suggests elimination of the facility up front rather than accommodation of the offending practice and/or its waste by-products.

Recognition of environmental LULUs and the organized resistance to them has increased since the 1950s due to the post–World War II introduction of chlorinated hydrocarbons in the production process, which are linked to health problems (e.g., at Love Canal and other Superfund waste disposal sites). Another issue concerns the spatial separation of the site of production from residential areas, an idea dating from the late 19th century, in which homes are often portrayed as a refuge from the consequences of factories and other sites of work. Such separation is now under attack as the continued expansion of the forces of production, and the ensuing negative externalities of production (e.g., noise, waste, and pollution), has invaded these residential sanctuaries.

LOCATION-ALLOCATION MODELING

Though often used to refer to more general location-theoretic constructs, location-allocation modeling is a specific class of spatial optimization model where two simultaneous decisions are being made about where a facility should be sited (location) and what entities/areas should be served by the facility (allocation). Geographers have made important and sustained contributions to this area of research, developing and extending mathematical models, devising effective solution techniques, and applying models to public and private sector planning problems. Prominent geographers working in the area include Charles ReVelle, Gerard Rushton, Michael Goodchild, and Richard Church, among others.

A location-allocation model locates a multiple number of facilities and allocates the demand served by these facilities so that access and/or system service is as efficient as possible. This definition recognizes the significance and necessity of optimizing a system on the whole in a coordinated fashion, in contrast to one-at-a-time addition of a facility when multiple facilities are sited.

Many different types of facilities are possible in a location-allocation model. In retail, a facility could be an outlet, store, warehouse, restaurant, and so on. Facilities associated with emergency services could include not only fire and police stations but also ambulances, warning sirens, disaster relief centers, and so on. Potential facilities could be schools, libraries, or even public pools and salt pile storage sites for road maintenance. Depending on the type of facility, examples of demand to be served could be stores receiving merchandise from a warehouse, neighborhoods being serviced by a school, or homes/businesses

being protected by a fire station. Given the facility and demand types, the location-allocation problem involves selecting facility sites (location) and prescribing which demand is served by what facility (allocation). Of interest is accomplishing the location and allocation in such a manner that system service is as good and/or efficient as possible. System service then is characterized in terms of economic efficiency.

A location-allocation model is a mathematical representation of a planning problem consisting of decision variables associated with location and allocation choices, the objective(s) to be optimized, and the constraining conditions that must be satisfied. The model is specified in algebraic terms as a series of linear and/or nonlinear functions. Some prominent location-allocation models include the simple plant location problem, the p -median problem, the capacitated plant location problem, and the transportation p -median problem. Of course, there are many other location-allocation models, some extensions of these basic problems.

There are two primary variants of location-allocation models, distinguishable by their spatial representation of potential facility locations. One variant allows facilities to be located anywhere in continuous space. Facilities are therefore considered to be feasible at any location in space. Travel through space is often assumed to occur in a readily defined manner, such as Euclidean or rectilinear distance. In contrast, the other primary variant assumes that facilities are only allowed at discrete locations. That is, facilities are limited to a finite set of potential sites. As a result, travel through space is assumed to take place through a transportation network consisting of nodes and arcs. Other distinctions of location-allocation models include capacitated versus uncapacitated facilities, stochastic versus static demand, and complete versus partial assignment of demand to a facility.

Depending on the location-allocation model of interest, the problem solution may be accomplished by applying an exact or heuristic approach. An exact solution approach is one where an optimal solution is guaranteed by the method. That is, it is possible to prove that the solution is the best possible and no other solution exists that is better. Examples of exact approaches include enumeration, linear programming, and integer-linear

programming. A heuristic solution approach, on the other hand, is one where feasibility is usually ensured (all constraints satisfied), but there is no guarantee of its quality. More specifically, a heuristic is a strategy-based approach that typically employs rules-of-thumb procedures to obtain a solution, preferably of high quality. Examples of successful heuristics applied to location-allocation models include alternating heuristic, interchange, simulated annealing, tabu search, genetic algorithms, and so on. A general finding is that exact approaches typically require considerable computational effort and can be limited in the size of problems that can be solved, whereas heuristic approaches are often capable of deriving good solutions quickly but with uncertainty about solution quality.

Location-allocation models continue to have practical relevance in planning, policy, and decision making but are also viewed as important because they can be used to represent other location-theoretic constructs, such as coverage models. Nevertheless, location-allocation models have proven to be challenging to solve in practice. Part of this difficulty is attributable to the complexities of dealing with geographic space and spatial relationships, but it is also the result of large problems being associated with better-quality, more detailed spatial information managed using geographic information systems (GIS). The continuing challenges in location-allocation modeling will be its use in new application contexts, the extension of existing models to account for enhanced problem realities, the development of heuristics to solve larger planning problems more quickly and efficiently, and further development of exact approaches for model solution.

LOCATION-BASED SERVICES

Location-based services (LBSs) have emerged primarily due to the availability of, and the possibility of coupling, “location,” “mobility,” and “context” information. Of these, location and mobility play central roles, and context describes the environment for the process of decision making in LBSs. LBSs are different from conventional geographic information systems (GIS) in that they feature mobility and the possibility of position determination while mobile. In other words, spatial decision making in LBSs is based on mobility and position, which involves dynamic locations of people and objects. An example of LBS is a navigation system in which a user’s location (“location”) is continuously (“mobility”) computed for the purpose of finding routes (“context”), among other things. LBSs, in general, could provide answers to questions such as the following:

- Where am I located at any given time with respect to another given location?
- Where are the locations of given people/objects with respect to my current location?
- Where is the nearest location of a specific person/object with respect to my current location?
- Is my location within a given proximity to a certain person/object?

As is clear from the above questions, LBSs must be able to provide “location” and “mobility” information and use them in a “context” to reason and make decisions.

Figure 1 highlights the types of features LBSs support and the types of technologies they use. The green circle highlights the features typically supported by LBSs, which include localization,

Figure 1 LBS features and technologies

Source: Author.

mobility, accessibility, visualization, scalability, and spatiotemporal modeling and analysis. The localization feature is for finding a user's location, which could be requested at fixed intervals or on the fly. It is worth noting the difference between position and location, as well as their relation to localization in general. By *position*, we refer to coordinates (e.g., latitude and longitude) as computed by a positioning technology. By *location*, we refer to a place to which the position belongs. For example, the coordinates of a car as determined by a navigation system give the position of the car and the road segment constituting the location of the car. The access feature is for accessing information and functionality remotely from the

user's current location. The visualization feature is for presenting location and context in a meaningful way to the user. The scalability feature guarantees solutions with acceptable response times regardless of how much information is being computed for decision making. For example, a task in one location may require a much larger amount of data for computation and visualization than would be needed in another location. The spatiotemporal modeling and analysis support efficient reasoning and decision making at a given location and within a user-specified context.

The blue circle in Figure 1 highlights the common technologies on which LBSs are based. Each category of technologies is for implementing one

of the features in the green circle. Geopositioning technologies are for implementing the localization feature—that is, finding the position and location of people and objects. The types of geopositioning technologies used in LBSs include global positioning system (GPS), radio frequency identification (RFID), and Wi-Fi, among others. Most such technologies provide position information that, depending on the application/service at hand, could be converted to location. Mobile devices are used for implementing the mobility feature and include primarily personal digital assistants (i.e., handheld computers) and cell phones, especially smart phones. Wireless communication allows LBS users to access data and other relevant resources remotely from various sources, such as LBS providers and third-party vendors. Mapping is a predominant form of visualizing information. *Infrastructure* refers to the underlying set of platforms and components required for the LBS. One example of such a LBS platform would be the Android system by Google. GIS, general purpose and specialized, is used for spatiotemporal modeling and analysis and for developing or customizing tools to support LBS decision making.

While LBS applications and services share common features and technologies, the implementation of each LBS application or service may require a unique infrastructure as well as specific sets of spatial and nonspatial data to meet the requirements of the underlying application or service. For example, an LBS used for advertising coupons for customers requires a different infrastructure and different sets of spatial and nonspatial data from an LBS that is used for education.

Since the early developments in LBSs, applications and services based on LBSs have been emerging continually and rapidly. Currently, such applications and services include the health, environment, education, and marketing domains, among others.

A recent trend has been to merge LBSs with social networks (SNs), resulting in a new research thrust called *location-based social networks* (LBSNs). LBSNs are social networks that can provide location-based information without computation but, instead, through the experiences of those who are trusted members in the network and who are willing to share their

location-based experiences. An example in health care is the work by Elizabeth LaRue and her colleagues called COMPANION; members of the network can assist a member suffering from depression. Another example of LBSN is the recent work by Hassan Karimi and his colleagues, where a framework for social navigation network (SoNavNet) can assist members of the network with navigation, points of interest, and route recommendations that are based on members' experiences.

LOCATION QUOTIENTS

Location quotients are a simple, widely used technique, primarily in economic geography, to measure how specialized the structure of the economy of a given study region is in comparison with a reference region (typically the country). They compare regional structural composition with that of the reference region by assessing an industry's share of a total regional economy relative to its share nationally. Usually, location quotients use employment data, although they can be used with any other kind of relevant information, such as output. Thus, in its simplest terms, a location quotient (LQ) can be defined as

$$LQ = \frac{\frac{\text{Regional industrial employment}}{\text{Total regional employment}}}{\frac{\text{National industrial employment}}{\text{Total national employment}}}$$

In mathematical terms,

$$LQ = \frac{e_{ir}/e_{tr}}{e_{ib}/e_{tb}},$$

where

- e_{ir} = employment in industry i in region r ,
- e_{tr} = total employment in region r ,
- e_{ib} = employment in industry i in reference region b , and
- e_{tb} = total employment in reference region b .

For example, to compare how specialized the economy of New York City is in banking in relation to that of the United States (base region), say that we are given the following hypothetical data:

- $e_{b,ny}$ = Employment in banking in New York City
= 350,000.
- $e_{t,ny}$ = Total employment in New York City
= 3,000,000.
- $e_{b,us}$ = Employment in banking in the United States
= 12,000,000.
- $e_{t,us}$ = Total employment in the United States
= 120,000,000.

Thus, New York's location quotient in banking would be

$$LQ_{b,ny} = 350,000/3,000,000 = 0.1166 = 1.166.$$

And the location quotient in banking for the United States would be

$$LQ_{b,us} = 12,000,000/120,000,000 = 0.10 = 1.00.$$

Thus, New York City's location quotient in banking indicates that it is more specialized (by 16%) in this industry than is the country as a whole.

A location quotient greater than unity indicates that the region is more specialized in a particular industry than is the country and is likely exporting the output of the industry; that is, it reflects a comparative advantage or economic base. Employment in excess of that necessary to yield a location

quotient of 1.0 is assumed to be driven by regional exports; high location quotients are thus associated with economic multiplier effects. A quotient equal to 1.0 indicates that the region and the country are equally specialized; that is, the region is neither importing nor exporting output in that sector. A quotient less than 1.0 indicates a region that is less specialized than is the country; that is, its degree of specialization is unlikely to meet local demand, and it is likely importing output in the industry. Obviously, if regions are more specialized in some sectors ($LQ > 1.0$), they will be less specialized in others ($LQ < 1.0$). The choice of reference region (e.g., a county vs. state or country) is important, for it can affect the outcome significantly. Such an approach assumes that local productivity equals that of the country as a whole; if the region enjoys a comparative advantage in the industry under question, it may be more productive than the country as a whole.

Location quotients can be mapped at a variety of spatial scales and over time to yield a simple portrait of how regional diversity and complexity change geographically and temporally. Maps of comparative advantage, for example, use location quotients. Obviously, such a measure is relatively crude, and more sophisticated measures of regional specialization exist. Nonetheless, location quotients are widely used in many urban planning and economic analysis circles because they yield a convenient and readily understandable portrait of regional specialization.

LOCATION THEORY

Location theory refers to a conceptual perspective widely used in economic geography during the 1950s and 1960s, primarily during the reign of the philosophy of logical positivism. Location theory exemplified geography as a spatial science, primarily concerned about abstract laws applicable under all circumstances.

Location theories in various forms shared a common focus on the centrality of models as bridges between the empirical world and the theoretical world of prediction and explanation. Models distill the essence of the world, revealing causal properties via simplification. A good model is simple enough to be understood by its users, representative enough to be used in a wide variety of circumstances, and complex enough to capture the essence of the phenomenon under investigation. Typically, models were developed, tested, and applied using quantitative methods. This approach to geography relied on a Cartesian view of absolute space, generally in the form of an isotropic plain in which space is reduced to distance and spatial variations only occur through transport costs. Essentially, location theory reduced geography to a form of geometry, a view in which spatiality is manifested as surfaces, nodes, networks, hierarchies, and diffusion processes. In short, this theory presented a view of space devoid of social relations.

Location theory developed close ties to neo-classical economics, spatializing economic relations through the use of cost-minimization and profit- and utility-maximization models. Often, it began with the assumption, and reached the conclusion, that unfettered markets were Pareto-optimal in nature. In some cases, location theory turned to cognitive psychology and behavioral geography to incorporate probabilistic models of behavior under uncertainty in studies of spatial cognition, decision theory, and suboptimality. This line of thought has been central to the discipline of regional science, a hybrid of economic geography and spatial economics.

Although it arose in popularity in the 1950s and 1960s, location theory drew on an older tradition of German economic geography that extended to the early 19th century. For example, Johann Henrich von Thünen (1783–1850), a

wealthy Prussian landlord, bought a 1,146-acre estate at Mecklenburg in 1810 and compiled data in 1821 for *The Isolated State*, the first model of land markets, which subsequently had important effects on studies of early land use (see Figure 1). In 1909, Alfred Weber (1868–1958), younger brother of the famed sociologist Max Weber, inspired the first industrial location theory. Weberian analysis centered on transportation costs, arguing that firms located where the sum of transporting inputs and outputs was minimized, leading them to be resource or market oriented. Walter Christaller (1893–1969) wrote his enormously influential dissertation *Central Places in Southern Germany*, in 1933, which founded central place theory, the conception of city systems in terms of a hierarchy of market areas distributing goods and services. This view of city systems posits them as retail centers (central places) that distribute goods and services to their surrounding hinterlands. Each good has a threshold, or minimum market size, and a range, or maximum distance consumers will travel to purchase it. A hierarchy of goods and services leads to a hierarchy of central places, with lower-order ones nested within the hinterlands of higher-order ones. Assuming an isotropic plain, a hexagonal network of market areas should emerge. Central place theory became the basis of most urban geography in the late 1950s and 1960s. Finally, August Lösch (1906–1945) contributed to location theory with the publication of *The Economics of Location* in 1939.

Location theorists developed and applied a variety of models to understand economic and demographic phenomena such as urban spatial structure, the location of firms, the influences of transportation costs, technological change, migration, and the optimal location of facilities. One group, gravity models, originated in Newtonian physics and became a highly successful way of modeling spatial interaction and predicting (though not necessarily explaining) patterns of interurban migration. Gravity models are widely used in studies of commuting and shopping, for traffic planning, and for models of transportation and communication. Similarly, network and graph theory became a useful way of mathematically describing the essential properties of networks of any kind, noting the accessibility of different nodes. It became a useful way of approaching transportation problems (e.g.,

Figure 1 The von Thünen model, developed in the early 19th century, has long played a central role in models of land use and continues to be useful today as a means of explicating how land markets maximize rents (profits). Although originally construed as means of analyzing agricultural land use patterns, it also has broad applicability to urban land markets, as illustrated by the varying uses competing for high-rent land at the urban core and progressively lower-rent land with distance toward the periphery.

the famous “traveling salesman” problem). Increasingly sophisticated mathematics invoked linear programming algorithms to develop location-allocation models, a convenient way to find optimal locations (e.g., for factories or stores) by minimizing transport costs subject to some constraint (e.g., total travel costs or time). Combined with geographic information systems (GIS), this approach is widely used in engineering and site location studies, such as for public services.

A somewhat different category of location theory concerned the process of spatial diffusion. Introduced by the famous Swedish geographer Torsten Hägerstrand, this approach was concerned with the ways in which innovations (e.g., new technologies,

information, and diseases) moved through time and space. Diffusion was held to be either contagious or hierarchical. The use of so-called Monte Carlo models introduced probability theory into models of the innovation adoption process. Originally designed to maximize the adoption of new techniques for development purposes, the topic is useful for epidemiologists and in marketing, where it is applied to analyses of consumer behavior.

There is no doubt that location theory made great contributions to human geography. It popularized the use of rigorous quantitative techniques such as multiple regression, log-linear modeling, factor analysis, discriminate functions, and entropy maximization and minimized armchair speculation by asserting the importance of testable hypotheses. Its models have found a wide array of applications, including traffic planning and retail trade analysis, and shaped development strategies during the heyday of modernization theory. Location theory uncovered a great deal of structure, pattern, and regularity in human spatial behavior, shedding considerable light on how markets function and allowing alternative scenarios to be envisioned and assessed. Coupled with GIS, this approach raised the analytical sophistication of economic and urban geography significantly.

Ultimately, however, location theory declined in popularity as logical positivism fell from favor. Its central problems included the fetishization of quantitative approaches; its increasingly unrealistic assumption of an objective, value-free observer; and its silence concerning social relations and social structures. The ontology of location theory is essentially atomistic; that is, it reduces the social to the individual through a process often called *methodological individualism* and, in so doing, tears variables from their social context. The focus on models led location theorists to ignore wider issues of class, gender, power, and struggle, positing instead an antiseptic, ahistorical, and sterile world of social order but not social change. Because it did not take subjectivity seriously, it deprived itself of any way to include human consciousness in all its complexity and richness. Location theory thus focused on appearances rather than causes, forms rather than processes, naturalizing the status quo and leaving itself incapable of being critical.

LOGICAL POSITIVISM

Logical positivism (often simply called *positivism*) has long been, and still remains, an enormously influential philosophy in geography and many other disciplines. It is commonly associated with the scientific method, which holds that scientific knowledge can be attained only through rigorous logical analysis and empirical evidence. It remains the dominant guiding epistemology of natural and physical scientists, although it has profoundly affected the history and contents of many social sciences as well.

Historical Origins

Although its history can arguably be traced as far back as classical Greece, logical positivism formally originated in the 1920s in Austria and Germany. Among its founding leaders were Rudolf Carnap, Moritz Schlick (founder of the Vienna Circle), Hans Reichenbach (founder of the Berlin Circle), Carl Hempel, Otto Neurath, Victor Kraft, Kurt Grelling, Philipp Frank, and Herbert Feigl. While the early logical positivists combined the logical concepts of Ernst Mach with the ideas of

Friedrich Ludwig Gottlob Frege and the British philosopher and mathematician Bertrand Russell, they were also inspired by Ludwig Wittgenstein's notion that philosophy's role was to provide a logical clarification of thought. As such, metaphysical speculation, that is, knowledge not grounded in logic and empirical evidence (such as religion), is automatically deemed unscientific. The growth of logical positivism in the United States came about during the 1930s. Many of the scholars behind the movement in Europe immigrated to the United States, where their ideas were well received. For example, in the late 1930s, Feigl, Frank, Carnap, and Hempel relocated to the University of Iowa, Harvard University, the University of Chicago, and the City College of New York, respectively.

Tenets of Positivism

Positivism differs from logical positivism in that the former originated from Auguste Comte during the period from 1798 to 1857 and aims to distinguish science from both metaphysics and religion. The two terms, however, are often used interchangeably. Logical positivism distinguishes mathematics and logic, and the analytical statements that can be formed from them, from empiricism. Positivism, more so than logical positivism, can be based on empirically accessible experiences of the world. Logical positivists hold that scientific knowledge does not rise solely from experience (i.e., positivism differs from empiricism). Logical positivists privileged mathematics in scientific decision making as the surest way to analyze data. Logical positivism recognizes only two types of scientific reasoning. The first is based on statements that can be verified empirically (a posteriori). The second is based on analytical statements of logic and mathematics that are deemed to be true or false by their mere definition and deduction (a priori).

Logical positivism encompasses two important concepts dealing with the structure of scientific theories: the differences between observational and theoretical statements (where truth is the correspondence between them) and between synthetic and analytical statements. These differences are used to explain deductive reasoning in scientific theorizing.

Positivists attempt to construct universal laws of explanation based on generalizations of empirical

patterns. For example, if Consumer A lives closer to a mall than Consumer B, then he or she is more likely to shop at that mall than Consumer B. Similarly, people tend to migrate more frequently over shorter distances than over longer ones. Because distance imposes costs on consumers and migrants, they collectively will tend to travel less frequently the farther away they live. From such observations, distance decay becomes an observed “law” of consumer and migrant behavior. All these notions combine to create “a Truth,” as opposed to “one truth” among many.

Advancements in logical positivism were based on two distinctions. First, analytical statements of truth are true *a priori*, that is, by their definition and association with logic, the formal sciences, and mathematics. Logical knowledge from mathematics, for example, is reducible to formal logic. Second, empirical statements of truths are empirically proven through hypothesis testing. Empirical knowledge includes physics, biology, chemistry, and the other natural sciences.

Since the rise of logical positivism, a significant advance was the rise of Karl Popper’s principle of falsification: Popper argued that science proceeds not by verifying hypotheses but by falsifying them. Only statements that can be falsified empirically are held to hold scientific value, and science proceeds not by verifying true statements but by eliminating false ones. Logical positivists are well-known for their emphasis on verification in that ideas or propositions go through a finite procedure to determine if they are true or false. Metaphysics and religion do not follow the same procedures of “truth telling.”

Critics argue that the verifiability criterion adopted in logical positivism is itself nonverifiable. Another criticism of logical positivism was that observations are inevitably couched in theoretical terms. That is, data are always theory laden (but not theory determined); the strict separation of facts and values is thus difficult, if not impossible, to sustain. There is also concern that truth changes as scientific paradigms shift: Positivism’s reliance on the correspondence theory of truth ignores the cultural and historical contexts in which true claims are established. As knowledge has increasingly come to be seen itself as a social construction, positivism’s portrayal of Truth as external to the social world came under mounting criticism.

Positivism in Geography

Logical positivism’s greatest influence in geography is associated with the quantitative revolution of the 1950s and 1960s, which included a heavy emphasis on laws and theories by geographers and a predilection for empirically based models. Traditional geography consisted almost entirely of regional description. The maturation of the logical positivist movement in the 1950s confronted geographers with the task of deciding in which direction to take the discipline, a conundrum exemplified in the adversarial stands of Richard Hartshorne and Fred Schaefer. Hartshorne advocated descriptive (traditional) geography, while Schaefer pushed for a new, scientific geography. Schaefer attacked Hartshorne’s empiricist emphasis on regional distinctions and instead favored nomothetic, lawlike statements to explain and predict spatial patterns. This attack encouraged geographers to rethink the direction of the discipline in a way that made it more theoretical and mathematical. As geography became more quantitatively based during the quantitative revolution of the 1950s and 1960s, it became heavily grounded in scientific rules of knowledge collection (e.g., random sampling) and hypothesis testing. Statistical techniques and abstract scientific models and theories evolved rapidly in number and sophistication.

The positivists were largely responsible for the introduction of numerous models into human geography, particularly the urban and economic parts of the discipline, including various quantitative models of migration (gravity models), diffusion of innovations, central place theory, location-allocation models, network analysis and graph theory, multivariate statistical techniques, and input-output models. However, it is now recognized that quantitative analysis and positivism are not synonymous (e.g., one can be a nonpositivist quantitative analyst, such as a quantitative Marxist).

Positivist thinking is often associated with neo-classical economic modeling in geography. In this regard, techniques have traditionally been borrowed from other disciplines and used to explain spatial processes and relationships. For example, the bid-rent curve, which originated in von Thünen’s famous land use model, is an example of simple, quantitative economic modeling. Waldo Tobler may have been the first to create a law (“Tobler’s First Law”) in geography based on gravity models,

using mathematical procedures to show that all phenomena are interrelated and that nearer things are more closely related than are distant things. Tobler's model has its inspiration in Newton's law of universal gravitation and has helped create statistical procedures unique to geography, known as geostatistics. Positivism was also instrumental in the growth of disciplines such as regional science.

The Decline of Positivism in Geography

Positivism is considerably less popular in geography today than it was several decades ago. Several schools of thought challenged its hegemony, including behavioralism, Marxism, and humanism. The notion that positive spatial science could provide realistic models was attacked because so many oversimplified models ignored historical context, social relations, power and conflict, and the dynamics of individual behavior. Marxists alleged that positivism's emphasis on positive rather than normative standards led it to be overly apolitical, antiseptic, and incapable of critically addressing pressing social problems. Quantitative models were held to be able to describe the world but not explain it, focusing on patterns but not processes. Positivism's emphasis on prediction as the hallmark of science was also criticized; prediction in the social sciences has always been problematic, and even in some physical sciences (e.g., ecology, geology), prediction is of limited value. The growth of humanistic thought led to a further critique of positivist models in geography as inappropriate when applied to the behavior of thinking human beings, with critics noting that the domains of emotion and subjectivity were not captured by quantitative analysis: In short, positivism did not provide an adequate account of the human subject and consciousness. Finally, the positivist assumption of a value-free, objective observer (the myth of "immaculate perception") was severely criticized; postpositivist thought emphasizes the embeddedness of knowledge within its social context. Nonetheless, despite these criticisms, logical positivism still lingers in human and especially physical geography, and it has had enormous impacts on the trajectory of geographic inquiry.

LONGITUDE

Longitude is the angular distance around Earth from a reference plane that defines a prime meridian. A meridian is synonymous with a line of longitude. Some conventions apply to angular expressions of longitude. One is that the angle is expressed counterclockwise with respect to the view from the North Pole to the South Pole. Sometimes, the angle from the zero meridian is stated as a value from 0° to 360°. The other convention is to express the longitude as a negative value from 0° to –180° west from the prime and as a positive value from 0° to +180° east of the prime. Longitude can be expressed in a variety of units (radians, grads, semicircles, arc seconds, or mils) and formats (+/– or E/W, to indicate the hemisphere; degrees: minutes and fractional minutes; or degrees: minutes: seconds and fractional seconds).

The determination of longitude on the surface of Earth is difficult because there is no physical meaning to any prime meridian. The prime meridian has been variously located in Amsterdam, Athens, Beijing, Djakarta, Berlin, Bern, Brussels, Copenhagen, the Canary Islands, Helsinki, Istanbul,

Lisbon, Madrid, Moscow, Oslo, Paris, Rio de Janeiro, Rome, St. Petersburg, Stockholm, Tokyo, Washington, and other places. It was not until the 1884 Meridian Conference that Greenwich, England, was selected as a suitable common prime meridian for the 22 attending countries, a decision based on the dominance of British charts in navigation. The Greenwich prime was defined as the center of the Royal Observatory transit telescope. Since then, most geodetic datums in use place the actual zero line of longitude a few tens of meters east or west of the original transit instrument. Even a datum used within Britain, such as the Ordnance Survey of 1936, places the zero line of longitude several meters away from the original Greenwich meridian. Without reference to a specific geodetic datum, longitude values will point to different places on Earth.

Since the establishment of an implied zero meridian in the 1960s by the *Bureau International de L'Heure*, modern geodetic datums fix the zero line of longitude not with a single point or line but based on a network of observatories around the world with longitudes whose offset from zero is defined. Geodesists may base their zero line of longitude on the International Earth Rotation Service's International Terrestrial Reference Frame (ITRF), which is updated to a new version every few years to account for continental drift. Modern global geodetic datums, such as the World Geodetic System of 1984 (WGS-84), are occasionally reset to ITRF, slightly changing the location of the zero line of longitude.

LOS ANGELES SCHOOL

In the late 20th century, an unusually large and fecund group of loosely affiliated, Marxist-inspired urban and economic geographers began to form in Southern California, particularly at the University of California at Los Angeles (UCLA) and the University of Southern California. This group, including notables such as Michael Dear, Edward Soja, Allen Scott, Michael Storper, and Mike Davis, played a key role in shaping urban political economy and injecting space into debates about the changing structure of capitalism. In particular, it was instrumental in theorizing the urban division of labor under post-Fordism or flexible production and, more broadly, in injecting space into the heart of all social analysis, helping dethrone historicism.

The so-called Los Angeles School upheld the greater conurbation of the region as the prototype of postindustrial, polycentric urbanization under advanced, globalized capitalism. This view was in contrast to the Chicago School of the early 20th century, which was located within, and concentrated on, the epitome of industrialized, unicentric urbanization embedded within a largely national market. In many ways, the school arose as an attempt to make sense of the bewildering changes unfolding across the region as Los Angeles was repeatedly reconfigured by massive social, technological, and spatial changes, which were generating a new urban regime of accumulation. Rather than an exception to long-held norms of urban analysis, Los Angeles became the new template for understanding other cities. Thus, for Soja, in a line used often in his works, “it all comes together in L.A.”; that is, Los Angeles is the exemplar of contemporary capitalism in all its gory complexity. As the ideas of the Los Angeles School became increasingly important in the discipline, other urban areas began to be dissected in similar terms. While it does not constitute a homogeneous whole—some doubt even the existence of such a school—certain commonalities run throughout.

Central to this line of thought was the primacy of production systems as the core of urban analysis, in contrast to the privileged status of individual decision making and residential space in both social ecology and neoclassical economic analyses. Scott's work laid the ground conceptually for the idea of

an urban division of labor organized around the input-output transactions of firms, which range from densely clustered, vertically integrated networks in the inner city to more dispersed, capital-intensive firms on the periphery. The historic shift into flexible production—a phenomenon identified rather early by some in the Los Angeles School—marked a significant transformation of firm organization and associated labor markets, ushering in broad-based changes in residential space, such as gentrification, and mounting social and spatial inequality, including homelessness. Intimately intertwined with this perspective was an account of the state, via various urban planning practices, as it accommodated the shifting imperatives of capital and sought to reign in the anarchy of the market. In this way, the Los Angeles School's view became an important stepping stone in the incorporation of regulation and regime theory, with close ties to subsequent work on world cities.

Moreover, this view noted, urban areas had become increasingly globalized—that is, situated within a worldwide division of labor or, more specifically, as a part of a global “necklace” of city-regions that propelled the international economy forward. Subsequent work elaborated on the role of interpersonal contact, face-to-face communications, and tacit knowledge in the creation of dense pools of firms locked into tightly bound networks. Firms and neighborhoods throughout Los Angeles, from the dream factories of Hollywood to the aerospace complex of Orange County to the immigrant clusters of Koreatown, were thus all simultaneously local and global, positioned between and across two scales that were more complementary than mutually exclusive.

For more culturally inclined scholars such as Michael Dear, Los Angeles exemplified postmodernism as an ideological stance and cultural practice, in contrast to the modernism of Chicago. Los Angeles was a pastiche, a complex text to be deconstructed, often with neologisms. The play of capital over space, and its relations with labor, generated a fragmented quilt of local communities, a leapfrogging checkerboard that defies easy generalization, and called for approaches that embraced the heterogeneity, hybridity, and fractionalized nature of urban space. Stepping aside from the convenient models of urbanism bequeathed by traditional urban analysis implied moving

beyond simple stereotypes about the Los Angeles region as a “set of suburbs looking for a city.” To quote Dear and Dahmann (2008), “In modernist urbanism, the impetus for growth and change proceeds outward from the city’s central core to its hinterlands. But in postmodern urbanism, this logic is precisely reversed” (p. 269). Thus, Los Angeles incorporated a diverse mix of architectural types, immigrant communities (notably including many Latinos and Asians rather than the traditional black-white chasm), political practices, cultural configurations, and lifestyles.

In offering this set of interpretations, the Los Angeles School did much more than simply substitute one model of urbanization for another (i.e., a Sunbelt version rather than a Midwestern one); rather, it redefined the meaning of the urban and recast the nature of urban theory itself.

LÖSCH, AUGUST (1906–1945)

The economist August Lösch was a major contributor to the formation of the body of knowledge combining geography and economics. With the geographer Walter Christaller, he made important contributions to the intellectual thread of location theory extending back to J. H. von Thünen and carrying forward to the formation of the multidisciplinary field of regional science.

Lösch's childhood years were spent in Heidenheim, Württemberg, Germany. He studied economics in Freiburg, Baden-Württemberg, Germany, with Walter Eucken (1891–1950) and later studied economics under the mentorship of Joseph Schumpeter (1883–1950) at Harvard University. Among Schumpeter's students were the economists James Tobin, Robert Heilbroner, Shigeto Tsuru, Nicholas Georgescu-Roegen, Abram Bergson, Paul Samuelson, and Robert Solow; the latter two received the Nobel Prize in Economics.

Schumpeter was important in August Lösch's intellectual development. Schumpeter wrote on the interdependence between demographic change, trade, economic development, and cycles of economic growth and on the importance of entrepreneurship in creating technical and financial innovations. Lösch's research dealt with the geospatial patterns of population, trade, and economic development. His most well-known contribution was *The Spatial Organization of the Economy* (1940). He acknowledged the

importance of the prior work of Christaller (1893–1969). Lösch generalized Christaller's work and explained it with formal economic logic. The contributions of both geographers stand in mutual support of each other.

Lösch developed his hypotheses in the logical positivistic style of the location analysis school pioneered by Johann Heinrich von Thünen (1783–1850). Lösch's conjecture was that spatial patterns of settlement can be described, and their interaction and location explained and predicted, based on their productive activities and their trade. He concluded, as had Christaller earlier, that in a spatial equilibrium, there would be a hierarchy of places. Higher-order places would produce goods and services that required greater numbers of people distributed over larger trade areas for their support. Lower-order places offer goods and services that require fewer people to be sustained. Lower-order places, with their smaller trade areas, are embedded among fewer higher-order places and their larger trade areas. Christaller's system of central places begins at the highest order, while Lösch's system begins at the lowest order.

Trade areas would arise in the shape of hexagons if the landscape were isotropic. Hexagons are the most compact of packable shapes. Christaller had shown that nodes of development are expected to arise on the apices, arcs, or interior of the trade area boundaries, depending on the initial assumptions of the model and characteristics of the landscape. Lösch demonstrated that the locations of Christaller's nodes were special cases of a more general geometry. Lösch's generalization predicted that surrounding a centrally located place, wedge-shaped zones of intensive higher development would arise, alternating with zones of comparatively sparse development. Because all places were geospatially connected, trade and people would naturally flow between the zones, but with the development advantage going to the zone that was "place rich."

LOVE CANAL

Love Canal, with its shocking images of toxic chemicals seeping into suburban basements and the emergency evacuation of a neighborhood, played a critical role in raising awareness of the dangers of industrial wastes. Love Canal was an abandoned canal in Niagara Falls, New York, where approximately 22,000 tons of chemical wastes were dumped in the 1940s and 1950s. After the dump's closure, a public elementary school, streets of modest single-family houses, and a public housing complex were built on and around the former canal. Over time, drums of chemical wastes began protruding through the soil, chemicals ponded on the surface, and choking odors filled basements and neighborhoods. When it grabbed national headlines in 1978, Love Canal dramatically increased the public's fear of chemical wastes, sparked the grassroots antitoxics and environmental justice movements, and led to the creation of stringent state and federal laws to address past contamination.

Hazardous Waste Management Before Love Canal

The first half of the 20th century witnessed explosive growth in the chemical industry as new chemicals were developed and production volumes increased dramatically. Unfortunately, some of the new organic chemicals were highly toxic and persistent in the environment. In the absence of federal hazardous waste regulations, the chemical industry often chose inexpensive waste disposal solutions such as open dumping or liquid-waste lagoons. Aware of toxicity issues, companies often attempted to control human

exposure through geographic isolation by fencing the disposal site, posting warning signs, and maintaining long-term trusteeship of the land. When that trusteeship broke down, situations such as Love Canal emerged.

Historical Geography of Love Canal

Love Canal, in the southeastern corner of Niagara Falls, was the site of William T. Love's failed attempt to generate hydroelectricity by connecting the upper and lower Niagara River, bypassing the Niagara Falls. Less than 1 mile of the canal was built before Love's financial backers dropped out, and he lost the site to mortgage foreclosure. In the 1920s, the canal was used as a municipal waste dump, and in the early 1940s, it was leased and eventually purchased by Hooker Chemical and Plastics Corporation (later Occidental Chemical Corporation) for chemical waste disposal. Between 1942 and 1952, Hooker Chemical drained the canal and dumped wastes containing at least 200 different toxic chemicals, including organic solvents classified as known or probable carcinogens, such as benzene, trichloroethylene, and tetrachloroethylene. In 1952, the dump was closed and covered with soil; in 1953, it was sold to the Niagara Falls School Board for \$1, along with a stern warning that chemical wastes were buried at the site.

Discovery of Contamination

Soon after residents moved into the neighborhood, there emerged isolated complaints of chemical odors or residues in basements and yards, along with minor explosions and spontaneous fires. Heavy precipitation in 1976 and 1978 brought rising water tables, spreading the buried chemical wastes. Environmental monitoring conducted by the State of New York and U.S. Environmental Protection Agency (EPA) confirmed the presence of hazardous chemicals in basements. Media attention, the frequent presence of environmental sampling crews, and a paralyzed real estate market led to calls for government intervention. Leading the call for help was neighborhood resident and grassroots activist Lois Gibbs, who circulated a petition, collected anecdotal evidence of serious health effects, and pressured reluctant politicians and government officials into

Evacuated Love Canal neighborhood

Source: Lawrence Potts.

addressing the contamination. In August 1978, the State of New York declared a public health emergency and ordered the permanent relocation of 239 families living along the canal. In 1979, the Love Canal Homeowners Association, led by Lois Gibbs, succeeded in convincing officials to expand the relocation order. President Jimmy Carter declared two federal emergencies, which provided funds for the relocation of more than 550 additional families in a wider 10-block area. By 1989, the residential relocations and the environmental investigation and cleanup had cost the state and federal governments \$140 million. After 16 years of extensive litigation, the Occidental Chemical Corporation agreed to reimburse \$129 million in costs. Contaminants at the site were contained with a synthetic liner and clay cap, and in 2004, the cleanup was declared complete. A follow-up health study conducted by the State of New York and the U.S. Agency for Toxic

Substances and Disease Registry concluded that Love Canal residents were not at higher risk for cancer but were at significantly higher risk for low-birth weight children, birth defects, and other adverse reproductive outcomes.

Influence of Love Canal on Hazardous Waste Policy

The 1970s were a decade of significant progress in regulating hazardous chemicals, including amendment of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) in 1972 and passage of the Resource Conservation and Recovery Act (RCRA) and the Toxic Substances Control Act (TSCA) in 1976. The RCRA established a system of regulations specifying the proper tracking, storage, transportation, treatment, and disposal of hazardous wastes from “the cradle to the grave.” Despite these efforts, a gap remained—past

contamination. Legislation addressing past contamination had foundered on controversies such as victim compensation and assigning liability. Given the recent passage of the RCRA and TSCA, the Love Canal incident was a source of considerable political embarrassment and galvanized public concern over abandoned waste sites. Spurred on by Love Canal and similar sites such as the Stringfellow Acid Pits in California and Valley of the Drums in Kentucky, Congress passed the Comprehensive Environmental Restoration, Compensation, and Liability Act (CERCLA) in 1980. The two primary features of the original CERCLA were its \$1.6 billion cleanup fund (the Superfund) and its strict, joint, several, and retroactive liability provisions. CERCLA's stringent liability regime, a direct response to Love Canal, created unintended problems of excessive litigation and stigmatization of a whole class of potentially contaminated former industrial sites known as *brownfield* sites. In addition to shaping hazardous waste legislation, Love Canal left its mark on the environmental movement. Lois Gibbs went on to found the Citizen's Clearinghouse for Hazardous Waste (renamed the Center for Health, Environment and Justice), an influential nongovernmental agency that supports communities in their efforts to address toxic hazards and promote environmental justice.

LYNCH, WILLIAM (1806–1865)

William Francis Lynch was an officer of the U.S. Navy who, in 1848, led the first successful expedition to explore and map the Dead Sea and established, for the first time, the depth of its surface below sea level.

Curiosity about the Dead Sea can be traced back to our earliest written sources for the region. Stories to explain the landscape and its bizarre mineral features found their way into the Bible (Genesis 19) in the form of the story of the destruction of the cities of Sodom and Gomorrah, located in the valley that is now the Dead Sea. And while the many visitors to the Holy Land often showed great curiosity about this lake, the legend grew that one could not enter it and live. Indeed, as late as 1816, two British naval officers, Charles Irby and James Mangles, traveled around the lake but were unwilling to set out on it, plumb its depth, or seek explanations for its minerals and salts. It is against this background of uncritically accepted biblical history, growing geological curiosity, but persisting fearful legends that it was a place of death that we have to view the first recorded explorations of the lake. The first was in 1835 by an Irish citizen, Christopher Costigan, who died shortly after rowing round the lake, leaving no notes. The second was in 1837 by the Royal Navy's Thomas Molyneux. He plumbed the lake, made notes, but died only weeks later.

In contrast, both in equipment and labor power, Lynch's was a far more careful affair. He studied the Sea of Galilee, followed the Jordan River south, and then made a careful survey of the Dead Sea, producing the first modern map and the first chart. All the while noting the region's geology, flora and fauna, and agricultural capability, the whole account was interspersed with notes on the customs and activities of all he met. In memory of the two earlier explorers, whose route he consciously followed, he named the northern point of El-Lisan "Point Costigan" and the southern one "Point Molyneux"—the latter has disappeared with the reduction in the lake's area, but the former, renamed Cape Costigan, survives on Survey of Israel maps.

Lynch's orders were to explore and survey the Dead Sea with the object of promoting scientific knowledge of the area and advancing the reputation of the navy. However, while he fulfilled these orders admirably, his hidden agenda was his real driving force, as becomes clear from his publications. In the face of increasing concern over the Bible's historical accuracy and challenges to it from geology and the fossil record, Lynch believed that his work showed that, at least, geology could not undermine the scriptures and that, indeed, further investigation might yield the ruins of the destroyed cities of Genesis 19. His work must, therefore, be located not only within the history of geological exploration but also within the history of Bible versus science debates. On his return home, Lynch published two distinct accounts of his journey: *Narrative of the United States' Expedition to the River Jordan and the Dead Sea*

(1849), which contains much of his theological thought, and the *Official Report of the United States' Expedition to the River Jordan and the Dead Sea* (1852), which has the character of a logbook; they need to be read together to appreciate that remarkable journey.

M

MACEachREN, ALAN **(1952–)**

Alan MacEachren is an American cartographer, an author, and a professor of geography at Pennsylvania State University. He is a pioneer in cartography and geographic information science (GIScience) research, known particularly for popularizing the term *geographic visualization* and setting its research agenda and more recently for establishing and directing the GeoVISTA Center at Penn State and launching the research initiative of geovisual analytics.

MacEachren argues that geovisualization (as it has come to be known) is more than the introduction of computing technology in the creation of dynamic maps and visual representations; it also considers the complex cognitive processes of representation users and the development of tools and theories that enable problem solving and knowledge construction. MacEachren presented the process of geovisualization as a complement to cartographic communication, which had long been the dominant paradigm for understanding map use. His landmark (Cartography)³ diagram, first published in 1994, categorized maps by three dimensions: (1) the level of interactivity, (2) the primary purpose/use, and (3) the degree to which the map is designed for individual or multiple users. Maps for geovisualization, for example, are typically highly interactive, reveal

unknown characteristics of the data, and are designed for a single or small number of users. This contrasts in each of these dimensions with the more traditional use of maps for communication. MacEachren is the author of the influential 1995 book *How Maps Work*, which links maps to cognitive linguistics, spatial cognition, and philosophy.

More recently, MacEachren has focused on the theory and practice of geovisual analytics, which extends geovisualization to modeling, reasoning, analyzing, and representing the large-volume heterogeneous databases that are encountered by those working in health, environment, national security, and other fields using georeferenced data. The geovisual-analytic approach, part of a larger interdisciplinary “visual analytics” research initiative, integrates statistical, psychological, and decision-science concepts, with an explicit focus on facilitating time-sensitive analytical reasoning to solve problems related to spatial data. Geovisual analytics is a major research theme at the GeoVISTA Center, which MacEachren and his colleagues in geography and information sciences at Penn State founded in 1998. The center has become an interdisciplinary research hub, focusing on spatial representation, multivariate spatial analysis, collaborative decision making, human factors, and many other GIScience issues. The expansion of geographic information technology to support its use by multiple individuals, groups, and institutions

simultaneously is of particular interest to MacEachren and his colleagues.

MACKINDER, SIR HALFORD (1861–1947)

Sir Halford Mackinder was a leading political geographer of the early 20th century, best remembered today for his “heartland” model of global geopolitics. Mackinder was a leader in the founding of academic geography in Britain. He was appointed the first geographer at Oxford in 1887 and started its School of Geography in 1899. In addition, he helped the University of Reading in 1892 and served as director of the London School of Economics from 1903 to 1908. Mackinder combined his academic career with political pursuits, serving as a Member of Parliament from 1910 to 1922 and chair of the Imperial Shipping Committee from 1920 to 1939.

Mackinder is remembered primarily for creating political geography’s most famous global geopolitical model, the heartland model. First developed in 1904, and refined over the next

40 years, Mackinder created a map of the world with three main areas: (1) *the Heartland* or *pivot area*, analogous originally to much of the Asian part of Russia but later extended to include most of the Soviet Union; (2) the *inner crescent* or *rimland*, the European and Asian areas surrounding the Heartland; and (3) the *outer crescent*, or everything else. Mackinder argued that the Heartland was the key to world power, that whoever controlled the Heartland could control the world. He based this argument on two factors: first, that over the sweep of history, those who had attacked and tried to conquer Europe had come from the Heartland and, second, because of its physical location on the Earth’s surface, the Heartland was impenetrable from attack on three sides, the east (Gobi Desert), the south (the Himalayas), and the north (Arctic Ocean), thereby making it the greatest defensive position on the planet. He argued that a naval power (i.e., Britain) would not be able to take over the Heartland. He suggested that the only way into the Heartland was through Eastern Europe and that, therefore, controlling Eastern Europe was the key to world domination.

Despite its long-lasting influence within political geography specifically and policy circles generally, there are major criticisms of Mackinder’s model. First, there have been critiques of his model specifically—for example, that a great defensive position in an inhospitable area with few people does not translate into an offensive strategy for world domination; that the growth in importance of airpower, nuclear weapons, and missile systems makes his model obsolete; and that the Heartland model’s Eurocentric-focus making the rest of the world irrelevant is problematic.

Beyond these specific issues, several critiques of Mackinder have been offered in recent years by students of critical geopolitics concerning such grand global geopolitical models that seek to “objectively” and from a “scientific, rational, neutral” perspective explain where power resides in the world and how it operates. First, Mackinder’s model is based in large part on the world’s physical geography—that is, how oceans and continents fit together. Such models ignore the billions of people who populate the world. As well, by placing Europe in the center of his maps, Mackinder made it appear “natural” that Europe

was the center of global power. In addition, Mackinder is purporting to present a global model of power offering a detached “view from above the clouds,” or a “god’s eye view” of the world and how it operates. However, while purporting to provide a dispassionate view of the world, Mackinder’s main interest was in making sure that the Germans did not challenge the British for global supremacy, with his main concern being that Germany would gain control over Eastern Europe. Thus, this supposedly scientific, dispassionate “god’s eye” view of how the world works was in reality a warning to Britain to look out for Germany and a possible alliance between Germany and Russia (thereby equating controlling Europe with controlling the world). Given Mackinder’s own political views championing the British Empire and its continuation as the leading global power, these warnings are not ultimately surprising.

Despite these problems, some Western policymakers in the post–World War II era saw Mackinder as a soothsayer for “predicting” the geographic contours of the Cold War. Mackinder and his ideas still have defenders today, for example, the influential late-20th-century and early-21st-century defense strategist Colin Gray; and Mackinder’s ideas have been extended to the domination and control of outer space, what one writer has referred to as “astropolitik.”

MAGELLAN, FERDINAND (1480–1521)

Ferdinand Magellan, or in Portuguese, Fernão de Magalhães, is well known as the first navigator whose ships circumnavigated the globe (Figure 1). Magellan was responsible for planning the journey, seeking financing, and surviving the subarctic winter of the straits in South America that bear his name; he was one of the first Europeans to set foot in the Marianas Islands and the Philippines. With Rui Falero, a scholar on celestial navigation, he convinced the Spanish king Charles I (later Emperor Charles V) and his Flemish advisors that the Spice Islands, also known as the Western Islands, the Moluccas, or *la especiería*, lay west of the line of demarcation of the Treaty of Tordesillas (1494) and thus were a Spanish, not Portuguese, possession. Albuquerque had conquered the Malaysian port of Malacca in 1511, explored the islands to the east, and used the Moluccas to initiate trade with China. In Spain, Americo Vespucci, Díaz de Solis, and members of the Council of Indies agreed with Magellan’s certainty that a strait opened to the South Sea. In the 16th century, these contested territories represented a highly desirable possession because of the abundance of clove, nutmeg, and cinnamon to be obtained there.

The 16th-century Dominican historian Bartolomé de las Casas wrote in his *History of the Indies* one of the most detailed descriptions of Magellan, including an account of his meeting with the Spanish chancellor Xevres while he was present at Valladolid. In this meeting, he came with a globe in his hand to describe with great certainty a new route to the Pacific that would place the Spanish Empire at a great advantage relative to the Portuguese. With the intervention of the Archbishop of Burgos, the one who had negotiated with the Catholic monarchs on behalf of Columbus, Magellan left with four ships, more than 230 men, and four court officials. The journey, as recorded in the several accounts by its participants, was treacherous. Some of the men took part in a mutiny at San Julián Bay, and most of them eventually died because of starvation, thirst, and scurvy.

Figure 1 Historical map of Battista Agnese in 1544 from the Portolan Atlas, showing the route Magellan took around the world and the route from Cadiz, Spain, to Peru, with overland portage across the Isthmus of Panama
Source: mapsorama.com.

After securing the first Spanish contact in the Philippines and the first conversion to Christianity, Magellan died on Mactan Island after a failed attack on a local native king. As with Columbus, the glory accounted in his biographies was largely due to the efforts of others; in the case of Magellan, only two vessels returned to Europe, the *Victoria*, under the command of Juan Sebastian Elcano, and the *Trinidad*, with Esteban Gómez in charge.

Magellan's journals, personal records, and letters written during his journey are lost. The most important narrative that has been translated into several languages is Antonio Pigafetta's *Primo viaggio intorno al mondo*, with maps well known for their inaccuracy. In addition, there are other firsthand accounts of the expedition, including Francisco Albo's *Diario ó Derrotero del Viage de Magellanes*. This account is useful for historians and geographers because it identifies the position of the "Unfortunate Islands" and it established that Amsterdam Island in the Indian Ocean was "discovered" by the *Victoria*. Also important are the anonymous Leiden narrative in Portuguese, printed in Coimbra as *Um Derroteiro Inédito*, and the Roteiro of "the Genovese pilot," which is known for the details of Magellan's death. Important in any discussions about Magellan's contributions is the Spanish cosmographer Diego Ribero's 1529 map that shows the extent of the Pacific Ocean, which Magellan named.

Magellan's contributions are key to the history of geography and trade in many ways. For the history of cartography, besides improving map accuracy and demonstrating the great distances between Europe and the Pacific islands, his journey stimulated the production of terrestrial globes that eliminated the edges of the world. With further exploration and conquests, the economies of the empire were strengthened. Magellan's expedition to the Spice Islands initiated the Spanish exploration of the Pacific Ocean, whose islands became a central stopping point in the newly expanded trade of the Indies with the new route from Manila to Acapulco.

MAHAN, ALFRED THAYER (1840–1914)

A late-19th-century American naval strategist and historian, Alfred Thayer Mahan is best known for his geostrategic writings on the geopolitical importance of sea power.

Born in New York in 1840, Mahan graduated from the U.S. Naval Academy and served as a captain in the U.S. Navy. In 1885, Mahan was appointed a lecturer at the Naval War College. Mahan's lectures served as the basis for his most influential work, his 1890 book, *The Influence of Sea Power Upon History*. Mahan argued that global geopolitical success was based on a country's sea power through its control of the oceans. Highlighting the importance of commerce and economic power, Mahan argued that a state needed a large powerful navy to protect and control commercial sea lanes. In Mahan's view, a country's potential sea power was based on a variety of factors, including its coastal physical geography (e.g., the length and nature of its coastline and harbors), the size of its population, and its national and governmental "character."

Mahan's argument about the primacy of sea power was influential in policy circles both in the United States and abroad. His rise to prominence occurred in the late 19th and early 20th centuries during the height of European imperialism and as the United States was itself in the process of becoming an overseas empire.

Mahan's work both influenced and was influenced by American and European actions. As part of his call for American control of the seas, Mahan advocated the U.S. takeover of Hawaii, the Caribbean, the Philippines, as well as Panama to build a canal connecting the Atlantic and the Pacific Oceans. Mahan also promoted the buildup of the American Navy, as epitomized in President Theodore Roosevelt's construction of the "Great White Fleet." His notoriety extended beyond policy circles to the general public through the many articles he wrote for popular American magazines of the time.

Beyond the United States, Mahan's writings also had important policy impact in the early 20th century. Mahan's work and policy prescriptions were important in England, Germany, and Japan, influencing naval buildups in these countries as well. Mahan is also credited with coining the regional designation term *Middle East* in 1902.

Mahan died in 1914 and is best remembered today within the history of early-20th-century geopolitics for his emphasis on the importance of sea power as juxtaposed to Halford Mackinder's land-based geopolitics.

MALARIA, GEOGRAPHY OF

Malaria is an infectious, vector-borne disease caused by the plasmodium parasite, which is spread from person to person by the anopheles mosquito. Acute symptoms of the disease include high fever, chills, headache, and fatigue, with common complications such as coma, anemia, and liver damage. Historically, malaria was widespread globally, but today it is confined mainly to the tropics, where it continues to exact a high toll on human health and development, with approximately 1 million deaths annually, countless infections and complications, and associated social and economic burdens. The vast majority of malarial infections and deaths occur in sub-Saharan Africa, as well as in tropical South and Central America, and South and Southeast Asia. The geography of malaria can be understood as the interaction between three interrelated geographies: (1) that of the anopheles mosquito, the vector for the disease; (2) that of the plasmodium parasite, the direct cause of malaria; (3) and that of human resistance to malaria, whether innate, acquired, or developed through culture and technology.

Since anopheles mosquitoes are the only means of transmitting the parasite from one person to another, their distribution has been the key factor shaping the geography of malaria. While there are several hundred species of anopheles mosquitoes, only about 40 are considered efficient vectors for malaria due to their ability to withstand the parasite and its anthropophilic feeding characteristics (i.e., a tendency to favor human over animal blood). Thus, in some locales where climatic conditions would seem to favor the presence of malaria, the absence of an efficient vector has left them malaria free. Nevertheless, malaria vectors are found in a wide array of landscapes, from tropical forests and savannas, to coastal marshes, to agricultural areas and cities. The most dangerous malaria vector, *Anopheles gambiae*, endemic to central Africa, sustains the world's highest rates of malarial infection and mortality.

Malaria parasites spend the sexual phase of their life cycle inside the anopheles mosquito. Insofar as the mosquito is cold-blooded,

the survival and reproduction of the parasite are sensitive to ambient temperature. Different species of the parasite are better equipped to handle low temperatures. *Plasmodium falciparum*, the deadliest form of the parasite, is less resistant to cold and as a result has always been most prevalent in the tropics. Another species, *Plasmodium vivax*, is capable of withstanding cooler and highly seasonal climates, which historically has allowed for a broader geographical reach into temperate zones such as the Southern United States, Southern England, Italy, and northwestern Argentina.

Finally, differences in human resistance to malarial infection help explain the heterogeneous geography of the disease. Genetic factors offer complete or partial resistance to infection for some ethnic groups. Most famously, the sickle-cell trait, found in about 20% of people in sub-Saharan Africa, reduces the severity of malarial symptoms. Many ethnic groups, including most Africans, have genetic immunity to *P. vivax* infection. In addition, partial yet impermanent resistance to malaria can also be acquired through exposure to infection. In areas where the prevalence of malaria is epidemiologically “stable,” such as sub-Saharan Africa, environmental conditions are optimal for year-round transmission of the parasite, but rates of immunity after childhood are very high. As a result, in such “endemic” regions, children suffer the vast majority of deaths from endemic malaria.

Today, there are many places where malaria could exist, or has existed in the past, but does not now. This differential geography can be explained mostly by the success or failure of efforts to control the disease. Prior to the 20th century, when a modern scientific understanding of malaria crystallized, cultural interventions that reduced the severity of malaria were unintentional. In particular, wetland drainage for agriculture—such as in England in the 1700s or the United States in the 1800s—eliminated the breeding areas for malaria vectors. From the early 20th century, malaria control became a public health imperative for colonial powers and developmental states. For several decades, it depended on a combination of strategies that included environmental sanitation (mainly draining wetlands), vector control, improving housing conditions,

and eliminating the parasite in the bloodstream through doses of quinine and other drugs. After 1945, international philanthropies and development institutions shifted to promoting house spraying with DDT, a potent insecticide, as the principal control strategy. Under the auspices of the World Health Organization, the Global Malaria Eradication Program was partially successful, with noteworthy achievements in Latin America and Asia. Over time, however, mosquitoes and parasites developed resistance to DDT and synthetic drugs, respectively, thus undermining the bases of the eradication program. Other financial, political, and logistical obstacles led to the near abandonment of malaria eradication programs.

As a consequence, malaria experienced a marked recrudescence from the 1970s onward. In some areas, such as the Amazon basin, the resurgence of malaria has accompanied agricultural colonization: Migrants, lacking immunity, enter areas where malaria is endemic, while at the same time transforming local land use and land cover (i.e., through deforestation) in ways that favor development of the local malaria vector (*Anopheles darlingi*). A similar dynamic has been observed in Malaysia and Africa. Since both vector and parasite are sensitive to environmental change, many scientists predict that global warming will expand endemic malaria zones, both poleward (i.e., away from the tropics) and to higher elevations. Today, GIS and remote sensing are central to research modeling the potential effects of environmental change on malaria transmission.

Malaria undermines the development prospects of the countries where it is endemic; as Sachs and Malaney (2002) note, “Where malaria prospers most, human societies have prospered least” (p. 680). The disease imposes a high economic and social burden due to the costs of prevention, drug treatment, and medical care; lower labor force productivity; and macroeconomic impacts from lower levels of tourism, trade, and foreign investment. There is also a circular relationship between malaria and underdevelopment, since desperately poor countries are ill equipped to address their public health problems. Recent philanthropic and multilateral aid programs have renewed and refocused efforts to bring malaria under control, employing strategies that take into

consideration the geographically variable character of the disease.

MALTHUSIANISM

Malthusianism in contemporary usage refers generally to the problems of food and resource scarcity created by and the limits imposed on human population growth. It refers to the work of the English cleric Thomas Robert Malthus, particularly his *Essay on the Principle of Population*, first published in 1798. Although debates about the relative merits and demerits of Malthusian thought are now fairly sterile, they are nonetheless relevant to discussions of international development, population geography, food security, and migration. The following sums up the history, influence, and limitations of Malthusian thought.

Malthus's "principles" of population were, first, that human population grows geometrically (e.g., 1, 2, 4, 16 . . .) and, second, that its ability to feed itself grows only arithmetically (e.g., 1, 2, 3, 4 . . .). Malthus allowed only two ways around this essential contradiction. With "preventive" checks, families, when faced with an inability to support their offspring adequately, should intentionally restrict their own fertility. For Malthus,

however, such a victory of—as he saw it, “reason” over “nature”—was trumped by a “passion between the sexes,” which was particularly indomitable in the lower classes. With “positive” checks, however, the relative fixity of food supplies compared with population itself limited population growth in the form of famine, disease, and human misery. This latter check was regarded by Malthus as an inescapable law of nature leading to population “equilibrium” and is perhaps the essential core of what we call Malthusianism, even as it is used today.

Malthus penned his essay in the midst of the rapid population growth associated with industrialization and capitalization of agriculture in Britain, as well as the violent social upheavals in France and America. He aimed his canons at radical utopians such as William Godwin and the Marquis de Condorcet, who believed that human reason and scientific advancement could transcend so-called natural laws and who consequently helped establish Britain's first welfare legislation. Malthus argued that social intervention in natural laws via social welfare would only temporarily stave off human misery, while encouraging population growth and lead to an even bigger calamity in the future. Consequently, he suggested, it was more humane in the long term to allow the poor to starve, though his critics cynically countered that this was a liberal construction meant to preserve the status quo, and hence his bourgeois lifestyle.

It is also notable that preventive checks for Malthus did not include birth control. Nevertheless, a number of 19th-century social reformers appropriated Malthus's ideas for decriminalizing birth control. These reformers were called neo-Malthusians; adding the prefix *neo* to *Malthusianism* in this early context (it has been used in different ways since) suggested a version of Malthusianism that accepted technological intervention in supposed natural laws, something Malthus himself would have repudiated as a threat to social order. Neo-Malthusianism retained all other basic tenets of Malthusianism. It had a wide range of political purposes depending on its various proponents, not the least of which were popular movements toward eugenics throughout Europe and the United States in the late 19th and early 20th centuries.

Malthus's ideas, in some form or another, experienced something of a revival in the mid 20th century, particularly as they were incorporated into international policy discussions. The preeminent economist John Maynard Keynes, for example, trumpeted Malthus in his critiques of European reconstruction plans after World War I. Malthusian doctrine was also frequently deployed after World War II by certain critics of international food aid and the diffusion of Western agricultural practices. For example, Garrett Hardin's notorious "lifeboat ethics" argument of 1974 was largely an extrapolation of Malthus's argument against helping the poor on an international scale. The biologist Paul Ehrlich also notoriously revived Malthusian thinking and applied it to nonfood environmental resources, including clean air and water, timber, and mineral resources, in his 1968 book *The Population Bomb* (republished extensively afterward). At the end of the Cold War, literatures concerning relationships between population, resources, and violence, variably termed *environmental security*, *resource wars*, or *green-war*, also took a predominantly neo-Malthusian approach.

Malthus remains a contested figure more than 170 years after his death. Neo-Malthusians typically contend that even if Malthus himself underestimated the agricultural potential of the Americans and could not possibly have foreseen 20th-century developments in agrosience, the ultimate finitude of natural resources suggests a theoretical ceiling *somewhere*. They often point to current global food and environmental crises as evidence. They argue that although Malthus may have operated with a crude understanding of equilibrium theory, more advanced ecological understandings of dynamic equilibrium suggest that the Malthusian predictions could still be realized.

Few scholars seriously contest that there exists some theoretical limit to population, but critics argue that this limit is not a presocial, inescapable natural law but rather a social construction born out of human economic, political, and cultural life. Promethean versions of this critique suggest that population growth is a problem inevitably addressed by economic and technological progress. Distributionist versions of this critique point out that adequate food supplies exist for the

global population even as projected into the future but that current local food shortages reflect distributional or pricing inequities resulting from unfair terms of international trade and lending, economic liberalization, and political corruption. Critics also see the global environmental crisis as a consequence of overconsumption in the developed world, not population growth in the developing world. In 1974, the geographer David Harvey suggested that the population-resource theory was an ideological construct, rather than unquestionable science, that works to preserve this unevenness. Furthermore, Malthusian limits to population are derived from theoretical beliefs that such a limit *must exist somewhere* and then mistaken for the empirical reality that they are supposed to model. Consequently, Malthusian limits are a product of human endeavor, not a limit on it.

MANUFACTURING BELT

The North American Manufacturing Belt emerged between 1830 and 1880, and well into the 1970s, industry located in this zone dominated manufacturing employment in the continent. This made the belt one of four broad industrial regions that

together dominated world industrial production through most of the 20th century. The belt was identified in academic literature in the 1930s and has been the subject of considerable research, mainly focused on its dynamics, geography, and subsequent decline and restructuring in the late 20th century.

Dynamics and Geography

When industrialization first gripped Canada and the United States, manufacturing took the form of many small establishments located in the Atlantic coast states and along the St. Lawrence River. These early enterprises were closely entwined with rural activities and added factory work to an industrializing countryside. Subsequent migration and urbanization, westward frontier expansion, and railroad and telegraph construction fueled industrial development within a westward-expanding industrial belt. In the American South, there was a relative retardation of industrial development because of weaker urbanization, limited investment in transport and communications infrastructure or farm mechanization, and a very different labor market. By 1870, industrial activity already covered the area subsequently known as the Manufacturing Belt, marked by Minneapolis and St. Louis in the west, Toronto and Montreal in the north, and Louisville, Cincinnati, and Baltimore in the south. In the period from 1860 to 1880, however, manufacturers in this region became functionally integrated into a continental geography of labor, market, and resource supply regions. By 1880, specialized establishments supplied products to wide market territories within the continent, factories depended on the skilled workers of well-developed urban labor markets, while their suppliers included not only mines, lumber mills, cotton gins, and grain elevators located outside the belt but also factories located in other industrial cities. Thus, the belt was formed through a process of regional specialization.

A spatially differentiated process of cumulative causation, operating on a continental scale, produced local and regional specializations within the belt on the back of initial advantages. Clear signs of manufacturing specialization are discernible even in 1880. The leading metropolitan centers for manufacturing each had disproportionate

shares of national employment in specific industries: In New York, it was garment production; in Philadelphia, textile production; and in Chicago, slaughterhouses and meat packing. Other local specializations included fruit and vegetable canning in Baltimore; musical instruments in Boston; furniture in Grand Rapids; tobacco in Louisville; glass, iron, and steel in Pittsburgh; and agricultural implements in Springfield, Ohio. A high-tech region emerged in New England associated with the American system of production, featuring interchangeable parts production and focused on the U.S. armories in Springfield, Massachusetts.

The belt developed a distinctive geography: An array of industrial regions comprising outer-ring cities and industrial towns clustered around metropolitan centers. Metropolitan centers provided finance, wholesale, warehouse, and transport services for manufacturers and served as innovation centers and information nodes. As early as 1880, 15 regional metropolises and 50 other industrial cities, all located in the belt, dominated U.S. manufacturing. A similar pattern emerged in Canada, where Toronto and Montreal, along with the many industrial cities, such as Hamilton and London, that constitute the Windsor-Quebec corridor, housed around 70% of national manufacturing employment for most of the 20th century. These industrial cities were distinctive: Their layout and pattern of development contrasts strongly with the newer metropolitan centers of the South and the West, such as Los Angeles, Phoenix, Houston, Denver, or Calgary. Specialized industrial districts emerged within the metropolitan cores. Some were keyed to major assembly operations, as at the Baldwin Locomotive Works in Philadelphia, which subcontracted parts production to adjacent suppliers in a way that enabled large-scale assembly of locomotives. Others featured the rental of machines and factory spaces to numerous enterprises, as in the Philadelphia textile industry. Yet others were the result of regulations concerning polluting industries and water rights, or localized agglomeration economies, such as those related to New York or Toronto garment manufacture. Historical geographers have been reinterpreting the dynamics, patterns, and causes of the suburbanization of manufacturing within metropolitan areas. This is largely because industrial facilities and associated

residential areas tended to be scattered 10 to 40 kilometres around major centers before the residential growth engulfed them. The belt featured diverse industrial and urban locales set in a dominant landscape of farms and forests, including satellite industrial towns, company towns, single-industry resource towns with processing industries, and small-factory villages. Workshops remained important even with the development of factory organization, machinofacture, and wage work. Thus, the belt's internal diversity complicates the metro-centered region model.

Beginning in the 1880s, a second industrial revolution associated with steel, electrical energy, and university-trained engineers altered the spatial dynamics of North American industry. New industries emerged, such as the automobile industry, which relied on the Manufacturing Belt, labor skills, innovation centers, capital, and suppliers. These industries tended to locate production inside the belt. General Electric and Westinghouse developed plants at Lynn, Schenectady, and Pittsburgh, while Ford and GM localized automobile production in southern Michigan. Corporations emerged and restructured their operations, closing older production facilities and deindustrializing some regions. While Canada's Maritime provinces faced deindustrialization at the hands of companies headquartered in Montreal and Toronto, leading U.S. firms established factories in Ontario, thus turning Canada into the first "branch plant economy"—a term coined in Canada in the 1920s. San Francisco emerged as the center of a substantial but distant industrial region. Some industries that supplied processed materials—oil, steel—to manufacturers, and that had developed first within the belt, relocated to take advantage of new resources. Steel production migrated westward and also developed in Birmingham, Alabama. Oil production in Texas and California outstripped the output in Pennsylvania. A new social organization of innovation and production came to characterize the belt. University-trained engineers, backed by specialized research labs, institutes, and universities, supplanted skilled workers as the innovators and controllers of factory production. Accountants, engineers, and lawyers professionalized the management of companies operating many factories from head

offices located in metropolitan centers. High levels of trade union membership marked the industries of the belt. Together, these processes restructured the activities that made up the belt and its relations with peripheral regions, intensifying production relations in some parts of the belt and closing plants in other places in a historical example of creative destruction that nevertheless reconfirmed the belt's locational advantages for many manufacturers.

Decline and Restructuring

In the early 1980s, the decline of manufacturing employment in the belt relative to the U.S. Sunbelt was widely recognized and attributed to a combination of government investments in the Sunbelt states and new realities for U.S. corporations under globalization. Massive government investments in manufacturing capability during World War II augmented the belt's industrial profile but also located new production facilities for military equipment in the U.S. West and South. These facilities became home to some of the growth industries under the next industrial revolution technologies: computing, telecommunications, and aircraft. Subsequently, federal government investments in freeways and housing, new migration patterns, and new amenities such as air conditioners contributed to postwar growth in the Sunbelt states. In a massive restructuring of the U.S. space economy during the 1980s and 1990s, corporations closed older plants, invested in new ones, or subcontracted production, sometimes to factories located in Asia, Mexico, or the Caribbean. U.S. Steel was transformed into USX, whose interests focused on construction and land development as steel mills were closed in the face of growing imports of cheap steel. The North American auto industry was restructured through competition from foreign makes, investments in new assembly plants, and vertical disintegration of the supply chain. As corporations adopted global network production systems, Manufacturing Belt states struggled to retain their former share of North American employment in manufacturing. John Deere, General Electric, IBM, General Motors, and Ford are some of the few major U.S. corporations with headquarters in the

Mittal Steel's Cleveland Works, May 20, 2005. Low-priced foreign steel has crippled an already fragile industry that had been dealing with high labor and materials costs for years. From 1997 to 2004, 45 steel manufacturers (about 40 % of those operating in the United States) went bankrupt. More than 85,000 jobs were lost from Western Pennsylvania through West Virginia, Ohio, Michigan, Indiana, and Illinois, according to the United Steelworkers Union.

Manufacturing Belt surviving from the heady days of innovation in the early 20th century. The results in the belt are diverse. They register as abandoned brownfield sites, pockets of high unemployment, outmigration, and struggles to retain or develop new identities after factory closings. They also figure as investments in a new economy: office towers, shopping malls, suburban housing, and some new factories. Together, these landscapes are witness to the latest rounds of creative destruction that reshape economy and society in North America.

The Manufacturing Belt was perceived as a distinct region, and one that was significant because of both its scale and its density, but the belt as a regional entity is also problematic. The belt is a product of analysis of the geography of manufacturing employment and investment in U.S. census returns. It is defined by the density of mills and plants, manufacturing workers, transport infrastructure, and power sites relative to other parts of the U.S. space economy. It was initially treated as a U.S. entity rather than a continental phenomenon. It was conceived as a system of cities but has been broadened to include industrial towns and an industrial countryside. Much of the research into the belt has focused on industrial districts and dynamics within its metropolitan centers. As the service sector expanded, manufacturing employment lost its cachet as the pivot of economic performance, so this is a historical sector whose fortunes have waned: The region is now better known as the Rust Belt or the Snowbelt. Yet the Manufacturing Belt continues to manifest in the higher population densities, older infrastructure, dense rail network, and other features of the Snowbelt states; in the regular division of the United States into geographic entities that permit rapid identification of the Manufacturing Belt states; and in studies of its “other”: the Sunbelt states and cities. In these ways, the belt remains an important reference point in the political economy of the United States and Canada.

MAP ALGEBRA

Map algebra (also called *cartographic modeling*) is a set of operators, operations, and rules governing the manipulation and analysis of spatial data using the raster data model. The raster data

model represents geographic objects and fields by tessellating space as cells, each of which is associated with a value indicating the identity, rank, or quantity of the phenomenon that occupies it. Map algebra treats raster layers as variables in algebra and calculates new raster layers by applying one or a sequence of operations using expressions.

Map algebra decomposes spatial analytic tasks into elementary operations that can be flexibly recombined. Elementary operations in map algebra are grouped into local, focal, and zonal categories based on the *spatial scope* of the operations. Local operations calculate on the cell-by-cell bases values in the output raster layer using cell values of the input raster layers at the same location. Focal operations calculate output cell values using the input cell values within their respective neighborhoods. A neighborhood is a set of cells that bear certain relationships to the center of the neighborhood. Zonal operations calculate output cell values using the input cell values within the same zones. A zone is a set of cells sharing the same measurement value. A zone may comprise one contiguous grouping of cells or of multiple groupings of cells.

Map algebra operations have been expanded on since their inception in the late 1970s and early 1980s. While the original spatial scope was confined to two-dimensional space, it has been later extended to three-dimensional spaces, in which two-dimensional cells are replaced by three-dimensional voxels. A similar extension was also made for spatio-temporal data sets, where the third dimension is time. Map algebra operations for vector fields, where cell values are vectors (magnitude plus direction) rather than scalar measurements, were also developed. Spatial analysis in the vector data model does not have an algebra counterpart, mainly because the analysis units in the vector data model are not spatially uniform. Recent research, however, has shown that the map algebra approach is also viable for the vector data model.

Although map algebra is a powerful spatial analysis language widely used in spatial analysis with geographic information systems (GIS), its operations do not comprise a set of atomic operations on which all complex raster analyses can be based. Also, the classification of the operations

into local, focal, and zonal groups is rather arbitrary. The search for a generic set of operations for both raster and vector data remains a challenge for researchers in GIS.

MAP ANIMATION

Map animation, in its simplest form, is the display of a series of static thematic maps sequentially to convey changes in a specific phenomenon. Geographers and cartographers use maps to display geographic information in an interesting way to show patterns of change in specific phenomena. This entry first presents a brief history of map animation and then examines the concept of visual variables used for animating maps. Map animation types are reviewed according to categories emphasizing change, location, or an attribute. Given the increasing use of computing technologies and the World Wide Web, online interactive map animations are highlighted.

History of Map Animation

Before computers and their related technologies became commonplace, geographers and cartographers had used techniques such as hand drawings of each map, and a camera recorded each map frame of the animation. Despite these early

technological challenges, geographers advanced the technology for animating maps. Norman Thrower, as early as in the 1950s, promoted the possibility and promise of animating maps for showing the distribution of the conversion of forests to agricultural land, the spread of populations over time, and the change in political boundaries. One of the earliest computer map animations was a three-dimensional portrayal of a population growth model of Detroit, Michigan, by Waldo Tobler in 1970.

Further developments in map animation were inhibited by the high costs of reproducing graphic/color images, the high cost of computer hard disk space, and the lack of animation software development. However, with continuing technological advances, the increase in the number of users, and the decline in the cost of computing equipment such as hard disk storage, computing technology use has blossomed in the past 20 years, and map animation has become much easier to design, use, and distribute. The technological advances in computing power and speed and animation software have allowed geographers to break through the early limitations of cost and time to display a plethora of information on maps.

Animations and Their Visual Variables

David DiBiase and his colleagues in the early 1990s showed how specific visual variables for static maps can aid in the development of map animations. Animating maps requires knowledge and programming of visual variables that involve duration, rates of change, and the order the maps are displayed in. Duration is the length of time a map is displayed. The rate of change is defined by m/d , where m is the magnitude of the change and d is the duration of each frame. By either increasing the magnitude or decreasing the duration, the animation would speed up, or by decreasing the magnitude or increasing the duration, the rate of change would decrease. The order is the sequence in which the map frames are displayed. In Figure 1, A shows the slower and the faster rates of change related to geographic position, and B shows a series of maps with increasing rate of change related to circle size.

Animation Categories

Map animations that emphasize change may display demographic shifts in the U.S. population center after each decennial census count. Animations that emphasize location may display the world map and the global locations of active volcanoes over a certain time period. Animations that emphasize attribute differences in the Earth-Sun Geometry would display the Earth's seasonal relative position to the sun. Many of these animations are helpful didactic tools to teach and visualize the changeability of a dynamic process, especially when the phenomenon is much larger than the human scale.

Technological Advances and Interactive Map Animation

Software tools such as Adobe Flash technology and Microsoft PowerPoint have made it much easier to animate a series of static maps. With the advent of the World Wide Web, the current robustness of broadband Internet connections, and inexpensive hard disk space, animated weather forecast radar maps and online interactive map animations have become commonplace. These online animations allow users to virtually visit interesting places across the world. Mark Harrower provides a good example of an interactive map animation of a Wisconsin Lakeshore Nature Preserve. Users can easily maneuver around the Preserve site and zoom in for detailed views and even see photographs of meadow or forest patches within the preserve.

Map animations have been increasingly integrated with geographic information systems (GIS) and satellite remote sensing so that graphic programs such as ArcGIS, Google Earth, and NASA World Wind can display multiple layers of geographic data and multiple scales of imagery to enhance the visual dynamism of the animations.

With all these technological advances in animating maps, the question is whether the map animation effectively engages the user. Map animations need to follow the proper map design principles and display the visual variable slowly enough for the user to understand the interaction or change. When map animation is effectively

MAP DESIGN

Maps remain the primary means of communicating arguments and exploring information in geography. Clear and compelling map design can propel research in geography, while poor design can hinder it. Good map design results from careful planning and consideration of choices that are made throughout the cartographic process. Some of these choices are informed by cartographic theories of abstraction and representation, while others are informed by psychological theories of vision and perception, and still others are informed by artistic theories of harmony and balance. These choices apply to both the map itself and the map image, defined here as the completed map document: a printed page, a journal illustration, an interactive animated Web application, or a visualization system designed for data analysis and exploration.

Aesthetic Considerations: Lessons From Visual Design

Effective cartographic design remains a subjective and artistic endeavor. Many principles of aesthetics, visual harmony, hierarchy, and balance have

been developed in the visual arts and apply to projects both in cartography and in other visual design fields (including graphic design, painting, and architecture).

Figure-Ground Relationships

First and foremost of the design priorities is the establishment of a visual hierarchy to convey the relative importance of the various elements on the map image. A hierarchy should be planned before the map is constructed, as it will determine scale and symbol choices. Important information on your map should stand out as *figure*, while contextual, less important information should recede (visually) to the background, or *ground*. Figure can be achieved by *closure*, by placing the figure entirely on the map image. Figure by *differentiation* is achieved by setting the figure apart from other elements—say, by a darker color or by richer detail. Figure can also be achieved by *contour*, that is, using drop shadows, stippling, or other techniques to make the figure appear closer to the reader (Figure 1).

Visual Balance

The map image can be thought of as a two-dimensional plane balancing on a fulcrum at the visual center, slightly toward the top of the image from the geometric center of the image. The addition of darkness to the plane adds visual weight that needs to be counterbalanced across the fulcrum by similarly dark, or weighty, elements. Not every square inch of a map image needs to be filled; some blank space is not only acceptable but appreciated. A map image should have such “negative” space distributed evenly.

Internal Consistency

Stylistic similarity of symbols, type, color, size, and other elements provides for cleanliness and organization of the graphic. The level of detail of line work and iconicity of symbols, for example, should be generally similar across the map and across themes. A particular form of internal consistency is *interparallelism*, which holds that straight-line elements on the map (e.g., “leader” lines, which connect labels to symbols; the labels themselves; or schematized representations of linear features) should be parallel to each other whenever possible.

Simplicity

A vital and somewhat counterintuitive cartographic guideline is that “what matters is not what you put *on* a map but what you take *off*.” In our age of easy-to-obtain data, maps are often generated with a glut of information that clutters the image, obscures the message, and confuses readers. Simplicity is almost always favored in visual design over complexity, even in information communication and visualization.

Cartographic Abstraction in Design

A large part of the art of cartographic design that occurs before pen is put to paper (or mouse to mouse pad) is finding appropriate ways to *abstract*

information to fit the audience and the purpose of the map. Cartographic abstraction includes strategies for data simplification through selection, aggregation, generalization, and classification and subsequent strategies for data symbolization through cartographic modeling, colors, icons, line work, and labels.

The Base Map

Often overlooked, the design of the base map sends subtle clues about the focus and accuracy of the map as a whole. In the creation of the base map, the cartographer determines the scale, projection, orientation, and extent of the map. The level of detail of the base map depends on its scale and message; features on the base map such as

coastlines, rivers, street networks, and labels should be *generalized* to remove unnecessary information that would mislead or detract from the main purpose of the map.

Selection and Generalization of Themes

For both reference maps and thematic maps, appropriate selection of the information to include on a map focuses the attention of the reader and allows associations to be made. Once the themes have been selected, attribute generalization such as classifying data into categories, aggregating data into spatial units, or eliminating details may also be appropriate to clarify the message. These techniques are often highly subjective and can greatly influence the arguments presented by the map.

Symbolization Strategies

Appropriate symbolization is also subjective, but convention provides most of the necessary design answers. Conventions can be defied on occasion to highlight unusual data or facilitate analytical reasoning, but in general, cartographers and graphic designers use symbolization conventions that are intuitive to most readers. In most scientific uses, simple geometric symbols are favored over complex pictorial symbols, which are more often used for tourism, advertising, or children's maps. Two aspects of symbolization—color and type—are complex and ubiquitous and are considered in particular below.

Color

Graphic designers describe color using (at least) three dimensions: hue, saturation, and value. *Hue* refers to the color's wavelength (red vs. green); *saturation* refers to the intensity of a color (electric blue vs. slate blue); *value* refers to the darkness of a color (pink vs. red vs. maroon). Color schemes can be used to encode kinds of relationships: A *sequential* color scheme, varying only in value, typically represents quantitative or other ordered data, while a *diverging* scheme, which starts with a dark value of one hue and proceeds through a light neutral color to a dark value of a different hue, is used to highlight opposing qualitative extremes. A *spectral* scheme, which appears

as a rainbow of hues, is often used on weather maps but is best reserved for qualitative data such as land use categories, ethnicity, or climate zones.

Perceptual limitations influence color choices: Most humans can differentiate no more than seven or eight different values of the same hue, a color appears darker if it is surrounded by light colors (and vice versa), and color-blind users cannot differentiate certain color pairs. The display device chosen may also influence color choices: Color printers tend to produce different (more saturated) colors from RGB projectors, and a color map likely to be photocopied needs to be designed so that the color encodings remain logical in black-and-white.

Type

Like color, type has several dimensions: font, size, stance, orientation, case, style, color, letter spacing, and several others. Well-established guidelines for the use of these dimensions to encode information on maps are found in cartography texts; only a sampling of these is reviewed here. Fonts on a map give a map style and spirit and should be used judiciously; fancy fonts are hard to read, and standard fonts appear dull. Convention holds that water features or other features representing flow are labeled using italic fonts, while stationary features are labeled with upright fonts. Space can be included between letters on maps to indicate the extent of an areal feature; typically, point and linear features' labels should not be "letter spaced" in this way. Type can be colored to allow the reader to connect the label with the symbol, which may be colored similarly, though some color combinations (black on yellow) are more legible than others (red on green).

Elements of a Map: Are They All Always Necessary?

While the attention of a reader of a map image should be directed toward the map itself, by examining existing effective map images, a reader will note the presence of several elements apart from the map itself, often on the map images. Some of these elements provide explanation and context, while others provide balance, identity, or visual interest.

Title

An economical and careful choice of words in a title provides succinct reference about the message of the map. A title is not always necessary: The title of the legend, for example, often doubles as the title of the map (e.g., “Median Household Income”). The title should be positioned and sized on the map image to draw the eye at first glance and then lead the eye to the focus of the map.

Legend

Careful design of the map legend is both vital and underappreciated. A legend is not always necessary (see Google Earth, USGS topo maps), but it is almost always needed on thematic maps and on reference maps if the symbols on the map are not obvious. Symbols in the legend should match the symbols on the map exactly. Elements within the legend should be spatially organized according to the same visual design principles, described above, that govern the map image as a whole.

Inset Maps

One or more inset maps can also be used to provide context and to fill blank spaces on the map. Inset maps are used for a variety of purposes: They can provide detail, orient the reader, show a complementary theme, relate noncontiguous areas (e.g., Alaska and Hawaii), or diagram nonspatial attributes (e.g., a histogram or population chart). Inset maps are usually set off from the main map with a visual separator, such as a line or a box, and if they are of different scales from the main map, this should be made clear.

Scale Indicator

A bar scale, representative fraction, or verbal scale (“1 centimeter to the kilometer”), like other map elements, is not always necessary, and on small-scale maps, a scale indicator may not hold true across the map. A scale indicator should be present if measurement of distance is important for the use of the map or if the scale would not be obvious to the intended audience. In this case, the scale indicator should be as small as is practical, and the measurements indicated should consist of round numbers with appropriate units (e.g., a tick mark every 100 km [kilometers], rather than

every 79 km, or 1:100,000 rather than 1:99,621, unless precise measurements are vital).

Directional Indicator

The “north arrow” should be used only in circumstances where the convention of north-up is violated or where the area mapped is unfamiliar to the audience. A directional indicator is also sometimes used as a logo for the cartographer or the mapping company and can thus serve as a stylistic means of establishing an artistic identity. Like scales, north arrows are often inaccurate except at specific locations, particularly on small-scale maps. If a north arrow is used, it should be as small as is practical.

The Neat Line

A thin line or linear design (e.g., a pair of lines or a border design) is typically used to frame the map. This provides closure to the map and gives an impression that one is looking through a window onto a scene. This “neat line” is used on print maps and those on computer screens (e.g., GIS and Web maps).

Map Design in the 21st Century

Decades before interactive mapping came into use, cartographers developed guidelines for “optimal” design, depending on the purpose and audience of the map. Today, many of those guidelines have been relaxed as map readers themselves have become cartographers. What was once a costly and time-consuming process—resulting in one printed map that was difficult to change once created—is now more fluid and less labor intensive, often resulting in ephemeral maps meant for use by a single person at one specific time. Of course, thousands of maps are created daily to be printed and displayed to a wide public audience, and in these cases, traditional map design skills are paramount. However, even a map that is rapidly and individually created in GIS or on Web mapping applications is still the result of myriad subjective and artistic choices of its creator, and the success of a map remains heavily dependent on good map design practice.

MAP EVALUATION AND TESTING

A map is an abstraction and simplification of geographic reality to scale, created by selecting the most pertinent information, translating it into graphic symbols, and, usually, projecting it on a flat medium (paper or a computer screen). More maps are now made and used than ever before. Technology allows their quick and easy production, even by the map users themselves, who may generate the maps they need, for example, within a GIS or with applications such as Google Maps or Windows Live Maps on the Internet.

The main reason for the abundant use of map displays is that they are a very efficient means for the communication, analysis, synthesis, and *exploration* of geographic information to solve people's geographic problems. There is neither an

alternative nor a better way to provide insight into geographic patterns, relationships, and trends. Electronic databases have taken over the traditional role of maps as a geographic data storehouse, but new map roles emerged in digital environments, for example, as a geographic interface to additional information ("clickable maps").

A potential problem is that today maps are not as effective and efficient as they could be. In the past, the production of maps was cumbersome and time-consuming. Maps were made by specialists (cartographers), who applied a user-centered approach in map design. This approach starts with a careful analysis of the purpose and use of the map, as well as the prospective user (group). Based on that view, decisions are made regarding geographic contents, map scale, map projection, and level of accuracy. Thereafter, cartographic symbols are designed and combined into a map in such a way that geographic information is properly communicated. The cartographic "grammar" applied in those design activities is largely based on knowledge obtained from systematic map-use research, informing about the ways in which map users perceive combinations of cartographic symbols and attach geographic meaning to them. Such a user-centered design approach should still be followed today, when maps are often made for noncartographers, as may be the case with maps in various thematic atlases and maps on TV, on the Web, or in newspapers.

Because of the emergence of new map types (e.g., dynamic and interactive displays) and because maps are often generated by nonspecialists, scientific map evaluation and testing are still very much required, not only to arrive at more efficient and effective maps but also to improve the hardware and software with which maps can be generated.

Two broad categories of map-use research may be distinguished: perceptual/cognitive and functional. The first type of research is mainly done to find out in general *how* maps, or their elements, work in geographic problem solving. Functional-map-use research is more specific and based on the clear assumption that a map is made for a particular purpose and that it is important to find out whether and to what extent a particular map meets that purpose (usability research).

Map evaluation and testing may have both a qualitative and a quantitative character. Qualitative research is particularly required when new products have to be tested and when there is no knowledge available on how people use these products to answer geographic questions. Think, for instance, of small map displays in mobile geo-applications on smart phones and handheld computers. There is also a need for quantitative measures telling us, for instance, how long it takes for a person to execute a particular map use task and how many map users arrive at the “correct” answer.

Several tools are available to collect the required test data. Four main categories of techniques of map evaluation and testing may be distinguished: interview, questionnaire, observation, and product analysis. An interview with map users may take two different forms: structured and unstructured. During an unstructured or in-depth interview (which may also be executed with a focus group representing map users), questions are formulated spontaneously, albeit within an interview framework. The advantage of unstructured interviews is that a lot of in-depth information can be gathered when little is known of the geographic problem-solving process under investigation. But their disadvantage is that it is difficult to compare the answers obtained from different users. Comparability of data is afforded by structured interviews and written questionnaires directed toward the functioning of map displays.

To obtain useful and comparable results through questionnaires and interviews, it is recommended to have the users actually execute one or more tasks with the help of the designed map(s). The outcomes of these tasks, which could be answers to geographic questions, and also maps generated by the users themselves, can be a subject of product analysis. In evaluating existing map displays, cartographic experts use the same cartographic knowledge that is applied in the user-centered map design approach referred to above. Such evaluation, performed by experts, is called heuristic evaluation.

Information about the functioning of map displays cannot only be derived by analyzing the outcomes of task execution. It is also important to investigate the map-use process itself. Interviews and questionnaires may be applied here

again, but there is a potential problem of subjects feeling inclined to interpret and rationalize their problem-solving behavior. Moreover, test subjects may be steered too much into directions predicted by the investigator.

These problems do not occur if information is obtained by participant observation while the map is being used. Verifiable data may be collected with special recording equipment that also makes it possible to carefully analyze the observations at a later stage. Examples of possible recording techniques are video, registration of eye movements and brain activities, and screen logging. One problem with these techniques is that the analysis of the outcomes cannot provide complete in-depth information on the cognitive processes that take place in the minds of the subjects. After all, we want to know not only what the map users are actually doing but also why they are doing it and what they are thinking when things go right or wrong. For this purpose, the think-aloud method, in which map users are asked to verbalize their thoughts when executing particular problem-solving tasks, is appropriate.

MAP GENERALIZATION

The capacity to comprehend the physical world depends on our capacity to model it. Given the complex interplay of multiscale processes (both human and physical), it is critical that we model it at multiple levels of detail and that we have the capacity to understand and model the interaction of these processes *between* scales. In many

respects, a map is a model: Within a set of constraints, it seeks to reveal scale-dependent patterns that arise from the complex interplay of those processes.

Traditionally, it has been the preserve and responsibility of the cartographer to abstract and visualize the world in all its forms, at various levels of detail, both topographic and thematic. Attempts to automate the cartographic design process (the craft and the science of the human hand) have highlighted the complexity and challenges of modeling and visualizing the world. This task has been made even more complex as a result of the introduction of technology that has created a fundamental paradigm shift in how we use, explore, and interact with geographic information. Where once the map reflected all that we knew, now the digital image has become a looking glass to the digital database—one that stores geographies of the world, at multiple levels of detail, and supports functionality far beyond that of the static page. It is this paradigm shift that has spawned new visualization methodologies and exploratory data analysis techniques. But technology has not obviated the need for good design, that is to say, efficient and effective ways of conveying as many ideas as possible, in the shortest time and with the least amount of ink—both beautifully and hideously illustrated in the books of Tufte.

Attempts to mimic the cartographic hand have had mixed success. Various approaches (most recently, agent-based modeling) have tried to deal with the fact that design is a complex decision-making process. We need the “eyes of the cartographer” to evaluate designs, and various cartometric techniques have been developed to measure content, generate candidate designs, and evaluate map output. Ideas concerned with data modeling and database design have gravitated toward the concept that we should store and maintain geographic information at the finest level of detail and, through the process of generalization, create multiple representations at different scales (i.e., multiple levels of detail). This paradigm has replaced ideas that echo past approaches to map series production—in which a set of independent databases were created, each of a predefined and fixed scale, each requiring its own maintenance

and update. The new model is one in which updates are made once, and if the right multi-scale model underpins the data model, any change at the fine scale can automatically “trickle through” the smaller scales, making changes and updates where necessary.

This entry expands on conventional approaches to automated mapping, beginning with a discussion of model and cartographic generalization. Through illustration, the entry highlights the importance of evaluation and analysis techniques to support map generalization.

Model and Cartographic Generalization

Many national mapping agencies (such as Britain’s Ordnance Survey or the U.S. Geological Survey) continue to print paper maps at national coverage, at a variety of fixed scales. Figure 1 shows a part of the city of Portsmouth, England, at three scales: detailed 1:25,000 scale (Figure 1A), 1:50,000 scale (Figure 1B), and 1:250,000 scale (Figure 1C)—all products of Ordnance Survey.

The idea is that in a highly automated environment, we can capture a detailed representation of the real world. This is referred to as the primary digital landscape model (DLM) and is typically mapped at 1:10,000 scale. Then, through the process of map generalization, we create generalized views of the world—maps that enable us to comprehend larger and larger geographical extents but in increasingly less detail (Figures 1B and C). The process of map generalization can be achieved through a combination of two very complementary methodologies—cartographic and model generalization. The process of model generalization involves modeling between fundamentally different phenomena. For example, instead of conveying pavements, trees, individual buildings, and gardens, we convey major roads, forests, and cities. These higher-level concepts comprise the features found in the primary model. The process of model generalization creates what are termed secondary DLMs.

In the process of cartographic generalization, we apply a set of techniques that resolve relatively subtle ambiguities to maximize the quality and clarity of the finished map—something that a

cartographer would describe as “the application of cartographic licence.” The process of cartographic generalization—applied to either the primary or the secondary model—produces the finished product. These ideas are summarized in Figure 2.

Model Generalization

Automating the process of model generalization has proved challenging and requires us to explicitly model the taxonomic and partonomic

relationships that exist between various geographic phenomena. These ideas tie directly to issues of data modeling and database design. It is common sense to interpret a dense region of buildings as being a town or a city. But in an automated context, we need to make this notion explicit within the model. Furthermore, we need to make explicit the range of scales (or levels of detail) at which it is appropriate to display a particular set of phenomena. In this way, and in combination with knowledge of the user’s task, the system knows when to represent the city as a dot (e.g., with the word “Edinburgh” next to it) and

when to represent the city in all its detail (such as in Figure 1A). It would take a huge amount of effort to create all the conceptual linkages that exist between all these scale-dependent phenomena. Thus, a lot of effort has been invested in trying to automate the process whereby phenomena are automatically grouped together—this is termed *data enrichment*. By illustration, we can say that we are all familiar with the concept and the function of a hospital. At a detailed level, we know it to be made up of wards, outpatient facilities, accident and emergency centers, parking lots, and laboratories. Algorithms have been developed that automatically “gather up” these various features to be able to collectively and generically represent this feature at smaller scales. Figure 3 shows the application of this algorithm in the context of a retail park (shopping mall) in Southampton, England, in which all the individual buildings and shared spaces have been collectively grouped together (Figure 3A) to be able to symbolize the retail park at a smaller scale (Figure 3B).

Cartographic Generalization

The cartographer applies a set of techniques that improve the legibility of the final product. For any map, the symbology has to be of a size discernible to the human eye, and this often means that a feature is represented larger than its geographical extent. For example, on A to Z road maps, the roads are distorted in width to fit the name of the street down their center. This increase in road width is at the expense of showing the blocks of buildings that lie between the roads. Separate from this process of exaggeration is that of displacement. Where a collection of important features are close together, it is necessary to marginally displace the features in order to discern their presence. Sometimes features are enhanced because of their importance (such as tourist features), and sometimes we symbolize features to overcome space constraints. Figure 4 shows seven techniques typically used to improve the legibility of a map; all these techniques come under the heading of cartographic generalization, each is shown with an example before and after application of the method.

Evaluation

The considerable research effort that has gone into developing techniques such as those in Figure 4 reflects the subtle and complex conditions under which these techniques are applied. Research in both model and cartographic generalization has reminded us that cartography has much to do with design and is a complex decision-making process. For example, when is it appropriate to displace a set of features in order to improve their legibility? At what point is it necessary to collapse a set of features (group them together) and represent them in some other form of symbology? At what point is the map so distorted that a particular technique can no longer be applied? What is the optimal order or grouping of these techniques? When is it no longer sufficient to apply cartographic generalization and instead it is necessary to apply model generalization techniques (in which we display a fundamentally different set of phenomena)? These sorts of questions have highlighted the importance of methods of evaluation. Evaluation is required at two key stages. The first is in the analysis of the various phenomena being mapped. This analysis is used to control both model and cartographic generalization processes. The second form of evaluation is assessing the final map's quality. Attempts to automate cartography have identified many qualities of the map that we wish to measure. We might want to measure the density of features in order to assess what space is available for displacement. We might want to preserve specific Gestalt properties among features—such as the orientation pattern of a set of buildings or the twisting nature of a mountain pass. All these qualities need to be measured since preservation of these qualities is often critical to the interpretation of the feature. Thus, the sinuous nature of a river might indicate a flat delta, or a large expanse of densely packed buildings might indicate a city. Techniques have been developed to model continuous regions (modeling the merging of adjoining regions), collections of discrete objects (i.e., using Voronoi diagrams), and the qualities of networks (i.e., using graph theory).

By way of example, Figure 5 shows a space-exhaustive tessellation of space, using a Voronoi

Figure 3 Modeling the function associated with a collection of buildings to derive secondary digital landscape models (example is a retail park in Southampton, England)

diagram based on the center point of a collection of buildings. In this particular instance, we have grayscale coded the cells according to the amount of space taken up by the building within its respective cell. This information was used to (a) model the extent of the city, (b) identify the characteristic grouping of buildings (pattern analysis),

(c) identify regions where specific cartographic generalization techniques can be applied, and (d) analyze the quality of the overall solution in preserving the varying densities across the region after generalization. In effect, these evaluation techniques mimic the “eyes of the cartographer” and are a critical component of any automated solution.

Conclusion

In attempting to automate cartography, early research focused on eliciting the rules that cartographers lived by but found that they live by exemplars, which makes it very difficult to model. Furthermore, it became clear that the human decision-making process was highly context dependent—full of exceptions. This has frustrated developments in automation. Research continues to focus on ideas of a “cartographic syntax,” a framework that makes explicit the linkage between the features of the map, their context, and the emergence of meaning among those features. Research has also produced a set of techniques that in varying degrees mimic the human hand and the human eye. All this research has

revealed just how challenging and creative the art and science of cartography are. While there is value in exploring this subject from a visual and cartographic perspective, it has also proved useful to see the map as a model—an abstraction that visualizes specific concepts and relationships among a set of geographic phenomena. It is this realization that is leading to much greater focus on the data model that underpins the automated creation of maps at multiple levels of detail.

MAP PROJECTIONS

Projections are manipulations of Earth's coordinates that are undertaken to represent the spherical Earth's surface as a flat plane. Projections are required to map the Earth on paper; the type of manipulation and the resulting output form a projection. Many diverse projections have been made, and they differ dramatically in appearance and properties. Most significantly, the properties of projections must correctly be matched with the purpose of the map, or else the map message may be distorted or inaccurately presented. Although projections apply mathematical formulas to position coordinates systematically, simple illustrative models are described here to clarify the output of the manipulations and to present classifications of projection types. Also, the resulting properties or characteristics of the projections and some specific projections and their strengths and weaknesses are discussed.

Projections build from a coordinate system and a datum. Most often, the coordinate system used is latitude and longitude, and this system provides a graticule or grid of intersecting lines, parallels and meridians, within which the data coordinates are plotted. In that Earth is neither perfectly smooth nor perfectly spherical, a datum provides a standardized definition of its shape as a model. So the datum describes Earth's shape around which the graticule is constructed, and the projection manipulates this grid to portray the curved Earth's surface on a flat sheet.

Visualization of Projections

The mathematical manipulations of projections are best understood by imagining a clear globe with the graticule printed on its surface, a light bulb used to illuminate the globe, and a large sheet of paper on which to project the lines from the globe using the light bulb. The positioning of the paper and the placement of the bulb in relationship to the globe provide for diverse configurations of the projected grid. This example depicts the categorization of projections.

The first of the variables in these models is the placement of the light bulb, providing different viewpoints. For the gnomonic position, the light

bulb is in the center of the globe. The placement of the bulb against the side of the globe makes the stereographic position. The light bulb can also be placed at infinity for the orthographic projection.

A second variable is the shape formed from the paper. The result provides a developable surface for the projection and drawing of the grid lines. The paper can be left as a flat surface to be planar. It can be wrapped into a cylinder to make the category of the projection cylindrical. A third configuration is to form a cone from the paper. This approach yields the development surface classified as conic.

A third variable is the aspect or the orientation of the paper or the developable surface to the globe. Regular orientations result in the simplest lines and are standardized based on the form made of the paper. For a planar projection, the paper is placed at a pole. For a cylindrical projection, the paper is wrapped around the equator. The conic version places the point of the cone at a pole. Rotating these placements 90° is a transverse orientation. An oblique orientation is any other placement.

Additional variations involve the configuration of the surface of the paper to that of the globe. The paper and the globe are tangent where they touch. This point is especially significant, because only where this occurs will the scale or size relationship of mapped features on the paper and the globe be identical. Tangency may be absent, may occur at one point, or may form a circle or ellipse, or two circles or ellipses. Usually, the regular orientation of the planar projection has tangency at the pole, and the cylindrical projection has tangency along the equator. However, the paper may be formed so that it intersects the globe. This form is described as secant. The advantage of creating a projection based on a secant developable surface is the increase in the area of tangency and the enhanced closeness of all points to being at the same scale as the globe.

Projection Properties

Projections inevitably involve distortion because the curved Earth's surface cannot be made flat. The characteristics maintained by projections are

the properties of the projection. Major properties include equal area or equivalence, and shape or conformality. No projection can be both equivalent and conformal. Minor properties include distance and direction.

An equivalent projection means that the size of small areas is comparable throughout the map. These projections are suitable to show dot distributions and the location of individual features where the distribution or relationship between the features is the central concern. Unfortunately, this capability is not inherent in many map projections.

A conformal map displays the shape of small areas by maintaining the angles within the graticule. These projections are particularly good for thematic maps communicating the characteristics of political units, such as choropleth maps. Sizes are progressively distorted.

The property of distance entails measurement from the central point of the projection rather than the accuracy of measurement between any two points. The property of direction means that the measurement of directions will match those on Earth's surface; however, once again, this quality ranges from correct to limited to absent depending on the projection.

Because of the inherent distortion in converting the curved surface of the Earth into a flat representation, no projection and no map accurately portray these four properties. Many projections are devised that strive to improve one property while sacrificing the others to varying extents. These projections are called compromise projections, because they forgo accuracy of one or more properties for improved qualities on other properties.

Sample Projections

Many projections have been devised. A few of the better-known ones and their strengths and weaknesses are discussed here to help illustrate the concepts that have been described and the importance of matching the use of the projection with the properties that are inherent to it. Cartographic tradition requires identification of the projection used to produce a map to be included in the legend or documentation.

Figure 1 Mercator projection

Source: Author.

The most common projection is the Mercator projection, named after its creator, Gerardus Mercator (Figure 1). It uses a cylindrical developable surface with tangency at the equator. Secant variations are also used. The Mercator projection is conformal and shows true direction, thus it is used for navigation charts. Parallels are straight but become more widely spaced with increased latitudes. The poles cannot be shown with the regular

aspect. Meridians are straight and evenly spaced. The greatest strengths are the rectangular shape, conformality, and ability to show true direction with a straight line drawn on the map. The weakness is misrepresentation of the area at high latitudes, thus exaggerating the size of areas such as Greenland and leading to misperceptions about the spatial relationships of distances between points at different locations across the map.

Figure 2 Mollweide projection

Source: Author.

The Mollweide projection, created by Carl Mollweide in 1805, is an equal-area projection (Figure 2). The parallels are both straight and parallel, placed to provide equivalence, and the meridians other than the central meridian are curved. Most shapes, directions, and distances are distorted, especially near the map edges. Strengths include the compact elliptical shape, which enables the polar areas to be represented. Weaknesses include the progressive shape distortion and inaccurate lengths of the parallels.

The Robinson projection is a compromise projection (Figure 3). Developed for Rand McNally by Arthur Robinson, a noted academic cartographer, it was used for about a decade by the National Geographic Society for their world maps. The parallels are straight and parallel, and the meridians, except for the central meridian, are curved. Although no projection properties are maintained, the straight parallels, the curved meridians (except for the central meridian), and the attempt to reduce distortions result in a pleasing and realistic appearance.

The Winkel Tripel projection (Figure 4) is another compromise projection combining two earlier projections and has somewhat less distortion

of the polar areas than the Robinson projection. The central meridian and the equator are straight, but other parallels and meridians are curved. The National Geographic Society substituted this projection for the previously used Robinson projection. Although no projection properties are maintained and the distortion is somewhat less than the Robinson, the overall shape is less pleasing.

The Plate Carrée projection is a compromise projection based on plotting the latitude and longitude coordinates as a simple grid (Figure 5). It is also called a rectangular projection; but in the traditional form, the grids are squares. All parallels and meridians are straight lines. The strength is the ease of use; however, the weakness is the failure to maintain projection properties. Many Web site maps display data in this format, which is inappropriate for density and pattern considerations. This projection is easily and best applied to small areas such as city maps, where the distortions will be sufficiently limited to make them insignificant.

The sinusoidal projection is an equal-area projection (Figure 6). The shape of these projections is variable, and this one is noted for its ornament

shape. The sinusoidal projection is often interrupted to use multiple central meridians to show the continental areas better. Parallels are straight, of appropriate lengths, and evenly spaced. Meridians are sine curves coming to a point at the poles. The right-angle intersection of parallels and meridians is absent, with the angle of intersection increasing toward the map edges. Thus, shapes are distorted away from the central meridian or meridians.

Some map projections are better adapted to mapping regions rather than the entire world. The Albers equal-area projection, for example, is satisfactory for mapping North America and good for showing the size relationships of areas (Figure 7).

It is conic and uses the secant method with two standard parallels. Meridians are straight, converging at the poles, and parallels are curved, forming concentric circles on the full cone. The two parallels make it best adapted to middle-latitude areas with wide east-to-west extent, so it is often used to map the United States, but it is less suitable for showing all of North America.

The Lambert conformal conic projection is used to show the shapes of middle-latitude regions such as North America (Figure 8). The cone-shaped developable surface uses the secant method with two standard parallels. Meridians are straight, converging at the poles, and parallels are curved, forming concentric circles on the full

Figure 8 Lambert conformal conic projection of North America

cone, with progressively closer spacing toward the poles. The suitable mapping areas are similar to those of the previously described projection.

Earth can be depicted as round, elliptical, square, dodecahedral, heart shaped, or double heart shaped, and even as an armadillo, the orthoapsidal projection. As the form is altered, the sizes and shapes of the ocean and land areas depicted are stretched and twisted. Mapmakers must be aware of the accuracy and limitations of the projection as they make their design choices; software programs offer diverse options with data tests for suitability.

Awareness of the type of projection applied aids in map reading and interpretation and may help identify those occasions when the ease of map production leads to inappropriate cartographic design.

MAP VISUALIZATION

Map visualization is an important component of geovisualization and refers to the dynamic representation of geospatial data and information for exploratory purposes and decision support. Unlike analog maps, which statically portray information to passive viewers, map visualizations today often require interaction with the viewer. The introduction of viewer interaction (e.g., changing map parameters such as scale or adding and removing map layers on demand and on the fly) with a cartographic production represents a fundamental change in mapping practice. Maps are no longer considered simply graphical inventories or informational artifacts; rather, the use of maps in interactive and exploratory fashion can enhance understanding, facilitate and extend scientific inquiry, and support decision making.

Recent advances in information technology, together with the proliferation of geospatial data, contributed greatly to this shift from static, cartographic maps to more dynamic geospatial representations and, more important, from a passive map-viewing audience to active spatial analysts

and mapping participants. In particular, the development, diffusion, and integration of geographic information systems (GIS), remote sensing (RS), cartography, and the Internet have revolutionized maps, mapping, and map visualization. Among the most notable changes to maps and mapping, which in turn spawned the tools, techniques, and field of geovisualization itself, was the shift from analog or hardcopy map production to digital cartography in the late 20th century. In addition to making map production more efficient, the digital tools and platforms on which geovisualization operates (e.g., GIS/design/statistics software, databases, network computers, the Internet) also facilitate the widespread diffusion, sharing, use, and viewing of geovisualization products, processes, and practices, as well as the development of the next generation of geovisualization techniques (e.g., mobile maps, interactive multimedia maps).

As information technology becomes more accessible, and as geographers and other professionals' monopoly on mapmaking disappears, map visualization itself becomes more accessible and more widely applied. Map visualization in the above-described sense is used by geographers and the scientific community, but it is also used across the public and private sectors (e.g., emergency responders, transportation engineers, planners, marketing companies). Furthermore, the emergence of neogeography, which refers to the creation and sharing of maps online for friends and visitors out of personal interest and curiosity, speaks to the continued diffusion of geovisualization tools and technology and to the changing population, behavior, and expectations of 21st-century mapmakers.

As geovisualization tools and techniques become more common, familiarity with geography and expectations from map visualization will also change. For example, the form and content of maps, which at one time were largely limited to the domain of the physical Earth, now extend into the realm of virtual worlds, cyberspaces, spaces of interactions, exchanges, flows, and networks, all of which are not necessarily bound to any particular geographic location. Moreover, this democratization of maps and mapping is not without its own complications or consequences. As data from myriad sources continue to

be collected and distributed, map visualization techniques will continue to highlight numerous questions on transparency and privacy and the broader implications of living in a geospatially enabled world.

MARCUS, MELVIN G. (1929–1997)

Melvin Gerald Marcus was born in Seattle, Washington, an environment that molded him as a geographer, environmental educator, and mountaineer. He claimed 52 first ascents by age 19, becoming the youngest person elected to the American Alpine Club. Recruited to Yale, he majored in geology while playing basketball and reaching the NCAA Final Four. While at Yale, Maynard Miller invited him to explore the Juneau Icefields, leading to a series of expeditions that fueled Marcus's interest in glaciology.

The Korean War interrupted his education in 1951. Volunteering for the Air Force, he piloted B-26 bombers. Postwar military duty in Japan prompted him to switch to a field that encompassed mountains, travel, and people. He left Yale, which had no geography department, and graduated with geography degrees from the University

of Miami (BA, 1956), the University of Colorado (MA, 1957), and the University of Chicago (PhD, 1964), where he studied the mass balance of the Lemon Creek Glacier, Juneau Icefields.

Marcus held teaching positions at Rutgers University (1960–1964), the University of Michigan (1965–1973), and Arizona State University (1974–1997). He was chair of the geography departments at the University of Michigan and Arizona State University. He also taught at Christchurch University and West Point on sabbaticals.

Marcus took students of all backgrounds into challenging field environments. Despite objections, he included women for the first time in the 1960s science expeditions to the St. Elias and Wrangell ranges in the Yukon and Alaska. His passion for environmental education led to two decades as a board member with Yosemite National Institutes, where he developed a geography-based environmental curriculum that eventually reached 40,000 students per year.

Marcus's research initially focused on glaciology and mountain climates, often in unexplored and unstudied settings. In the 1970s, his research expanded to include human-environment interactions, usually with an emphasis on human impacts on micro- and meso-climates, ranging from building effects on heat flux to land use impacts on dust storms. Later writings such as *Geography's Inner Worlds* examined the status of geography and geographic education.

As president of the Association of American Geographers (1977–1978) and in his presidential address, "Coming Full Circle," Marcus advocated for the importance of physical geography and commissioned the strategic plan that generated Specialty Groups, which were critical in keeping physical geographers within geography. He was vice president of the American Geographical Society from 1986 to 1996 and chair of the U.S. National Committee of the International Geographical Union, a position he used to influence the *Rediscovering Geography* report, which advocated for geography's role in the world.

MARGINAL REGIONS

Marginal regions are regions that are situated somewhere at the edge or at the margin of a system and are not part of the traditional center-periphery model. Marginal regions and peripheries are not the same. Marginal regions are also called associated regions, isolated regions, or dead angles. While centers and peripheries exist in more or less intense mutual relationships, these regions (or places) occupy different positions within the system. They can be categorized as follows:

1. **Associated region:** A place can lead a life of its own and yet be associated with a major center, such as the port city of a capital. There are close ties between it and the center but no unilateral dependency.
2. **Isolated region:** A place may have intense internal relations but little contact with the outside world, thus remaining isolated from it and living according to its own rhythm.

3. **Dead angle:** A place (or a region) can be situated off the main communication flow and lead a very introverted life at the edge of a system, lacking a development potential of its own.

Types 2 (isolated region) and 3 (dead angle) resemble most what we would call marginal regions. They may exist inside a polarized region but are not part of it.

Marginality can be encountered in various contexts and at a variety of scales. It has a distinctly spatial component. Socially marginal groups, for example, often congregate in specific locations, as exemplified by the dwelling areas of the Untouchables in India, the Ghetto for the Jews in medieval European cities, certain housing estates, and gated communities.

Ways of Looking at Marginality

Walter Leimgruber's attempt to understand marginal regions identified four different types of marginality: geometrical, ecological, economic, and social. Other possible approaches (political, cultural, risks/hazards, and perception) also exist, thus demonstrating the diversity of the concept and the various disciplines that would be involved in marginality research.

A purely materialistic perspective would define marginality by some threshold value of the gross domestic product (GDP) per capita. This restricted view is static and overlooks other manifestations. Social marginality cannot be reduced to the GDP. Marginality is not the end-stage of a process, but it may be of limited duration. A dynamic approach is therefore required. A suggestion could lie in the comparison of market integration and the level of productive forces. A region where both are low can be classified as marginal, and a change in one or in both parameters would lift the region out of marginality (Figure 1).

Another approach is based on the diversity of human societies, which "are not necessarily unified collectivities" (Giddens, 1984, p. 24). This diversity manifests itself in highly varied human behaviors, which define a social mainstream within which all individuals oscillate (Figure 2). Certain individuals' behavior, however, is located at the

Figure 1 Possible trajectories for marginal individuals over time. The degree to which individuals fluctuate from established social norms is temporally and geographically fluid.

Source: Leimgruber, W. (2004). *Between global and local: Marginality and marginal regions in the context of globalization and deregulation*. London: Ashgate. Copyright © Walter Leimgruber.

Figure 2 Marginal regions in the context of productive forces and market relations. Marginal regions tend to be peripheralized in terms of both productive capacity and their level of integration into wider divisions of labor.

Source: Leimgruber, W. (2004). *Between global and local: Marginality and marginal regions in the context of globalization and deregulation*. London: Ashgate. Copyright © Walter Leimgruber.

extremes of a society's range and may even reach considerably beyond it. Such persons no longer belong to the society's "mainstream" but are marginal persons. While the mainstream is relatively stable over time, marginal individuals can nevertheless have a long-term impact on the society in that they may bring about transformations; they are in fact essential elements of every society. "While the continued existence of large collectivities or societies evidently does not depend upon the activities of any particular individual, such collectivities or societies manifestly would cease to be if all the agents involved disappeared" (Giddens, 1984, p. 24). The sum of such marginal individuals can be called a marginal group or community.

From a political perspective, marginality can be associated with regions along political boundaries where the application of state authority ends, where the military function of a boundary is prevalent, and where investments are traditionally low. This kind of marginality can also be described as geometrical.

There is also a positive side to marginality that tends to be overlooked. Marginal subjects (individuals, groups) can be agents of social transformation and innovation. Indeed, persons who have brought about substantial changes were often socially marginalized (e.g., St. John the Baptist, Jesus Christ, St. Francis of Assisi). Even Einstein, in his outer appearance, did not conform to standard social expectations.

This variety of meanings is the reason why a wider approach

to marginality and marginal regions is required, an approach that helps revise the dichotomy between cores and marginal areas. One could also include the natural environment, which has become marginalized over the past few centuries due to the emphasis on the material well-being of an affluent society.

MARINE AQUACULTURE

Marine aquaculture refers to the farming of aquatic organisms in coastal or off-shore marine environments, involving controlled interventions to increase production by specific groups claiming ownership of the cultivated stock. Marine aquaculture involves the farming of a high diversity of aquatic organisms, including mollusks, crustaceans, fish, and aquatic plants, amounting to 240 reported species in 2004, cultivated in diverse environments (brackish and marine areas), with different technologies (cages, ponds) and a wide spectrum of production systems operated by distinct groups (individuals, cooperatives, corporations) in several regions of the world.

Production and Distribution

Marine aquaculture has been practiced for millennia, especially in Asian cultures, but it has grown exponentially since the 1980s in response to a widespread decline of the world's fisheries and increased consumption of aquatic species by

the developed nations. Aquaculture growth exceeds that of all other animal-food-producing sectors, at a rate of 8.8% per year since 1970 as opposed to 1.2% for capture fisheries and 2.8% for terrestrial meat production systems, but shows signs of leveling off, although high growth rates remain for some regions and species. Although most aquaculture production of fish, crustaceans, and mollusks is derived from freshwater environments representing 56.6% by quantity and 50.1% by value of aquaculture production aggregated, marine aquaculture production is significant and was reported by the Food and Agriculture Organization (FAO) to be 35.07 million metric tons in 2006, with an overall value of US\$44.8 billion, including all aquatic organisms and geographical zones. Of the world total, China accounts for 67.6% of the total quantity and 39.9% of the total value of marine aquaculture, thus dominating the marine aquaculture industry.

Much of the marine production consists of high-end finfish as well as relatively low-priced mussels and oysters, while brackish-water production is dominated by high-value crustaceans and finfish. The high diversity of aquaculture production is illustrated by the variety of species farmed. Aquatic plants and mollusks show the greatest rate of growth since the early 2000s, while mollusks and crustaceans show the greatest increase in value. Diadromous fish also show a stark increase since 2004. While these numbers illustrate the emergent trends in marine aquaculture, they also reflect the efforts by countries to improve their reporting systems. Geographically, marine aquaculture production and value is clearly dominated by Asia, followed by Europe and the Americas, while Africa and Oceania remain marginal.

Balancing Economic Growth With Environmental and Social Sustainability

Proponents of marine aquaculture argue that the industry provides an alternative to declining fisheries, enhancing the food security of local populations while providing employment and attracting economic investments in the host countries, often developing nations. China is the country with the highest number of fish farmers (4.5 million) in 2004. Other countries with a high number of fishers and fish farmers include India, Indonesia,

Figure 1 Top 20 nations most reliant on marine aquaculture, 2006

Sources: Adapted from Food and Agriculture Organization of the United Nations Aquaculture Statistics (2006) and EarthTrends GDP Statistics (2008).

and Vietnam. Employment in fisheries and aquaculture has been growing in low- and middle-income countries and declining or stagnating in the industrialized states. Most of the production of marine aquaculture comes from low- to middle-income nations. Marine aquaculture plays an important role in providing cash income and investments to developing countries and contributes importantly to the national economies of many developing states. Latin American and Asian states are particularly dependent on marine aquaculture, with Chile having more than 9% of its gross domestic product derived solely from marine aquaculture (not counting freshwater aquaculture).

Despite the importance of marine aquaculture to national economies, there are no reliable estimates of the actual returns of the activity to local communities and local producers. Marine aquaculture is heavily criticized for its environmental impacts on coastal wetland ecosystems and its mixed record in terms of social benefits to rural communities. Pond aquaculture in brackish systems has caused considerable loss of wetlands, especially mangroves. In Latin America, between 20% and 50% of mangrove destruction since the 1980s has been attributed to shrimp aquaculture expansion. Issues of water quality degradation, invasive species, and disease spread are also tied to the presence of high densities of aquatic organisms and the addition of feeds and antibiotics. Feed in

particular is controversial as it is often derived from fish and other aquatic organisms caught in the wild, thus adding pressure to the already over-exploited fisheries, instead of providing a solution. Opponents of marine aquaculture have therefore argued that its economic benefits mask considerable environmental and social costs.

Marine-aquaculture-related environmental degradation directly affects coastal communities, which experience declining returns in local fisheries and other wetland-related goods and services. Marine aquaculture also creates social tensions in coastal communities between those who choose to engage in the activity and those who depend on the formerly readily available wetland ecosystems. In that regard, marine aquaculture has facilitated the privatization of wetlands, limiting their use by the coastal poor. Additionally, small-scale producers have been unable to remain competitive when faced with large-scale industrial complexes with economies of scale, thus raising issues of equality within the industry itself. In response to these criticisms, the industry has started to establish best management practices (BMPs) in order to limit environmental and social impacts. These BMPs are seen by some small producers as another barrier limiting their entry into the aquaculture industry. Many small producers have limited access to credit or markets, thus restricting the extent to which they can conform to international standards and regulations. More work needs to be

done therefore to draw small-scale producers into national and international markets, while maintaining the integrity of the natural resource base on which both marine aquaculture operations and human populations depend.

MARK, DAVID M. (1947–)

A pioneer in geographic information science (GIScience) research, David Mark played a formative role in establishing the cognitive and linguistic foundations of the discipline. His early work on topographic data modeling also included seminal contributions to the development of triangulated irregular networks (TINs) and algorithmic flow modeling. He authored or coauthored more than 220 papers and played an instrumental role in establishing several national organizations and conference series to promote GIScience. A professor in the Department of Geography at the University at Buffalo, State University of New York (SUNY) since 1981, Mark received the University Consortium on Geographic Information Science (UCGIS) Researcher of the Year award in 2004 and was appointed SUNY Distinguished Professor in 2007.

Mark received his BA and PhD degrees in geography at Simon Fraser University in 1970 and 1977 and an MA in geography at the University of British Columbia in 1974. As an undergraduate, he proposed a correction for statistical analysis of the orientation of sedimentary strata, which is still widely used in geological studies. While a master's student, Mark began work on the TIN model of topographic representation under the supervision of Thomas Poiker (formerly "Peucker"). His rigorous comparative analysis demonstrated the relative effectiveness of TINs and contributed to their widespread adoption in geographic information systems (GIS). Later work on topographic analysis yielded the well-known D8 flow routing algorithm, which eliminated spurious pits from digital elevation models.

In the 1980s, Mark's research began to focus on the fundamental properties of geographic features and their representation. Papers on the fractal nature of geographic phenomena summarized for geographers the importance of scale dependence in measurement and the utility of recursive partitioning schemes. This period also witnessed

the beginning of a long-lasting collaboration with the philosopher Barry Smith to investigate the ontological constraints of geographic categorization. Questions of how people experience, cognize, and communicate with respect to spatial phenomena led to co-organization of a workshop in 1990 in Las Navas, Spain, which is often considered the birthplace of the cognitive and linguistic threads of GIScience.

Throughout the 1990s, Mark contributed to the emerging field of GIScience a series of reasoned investigations on spatial relations and experiential, cognitive, and formal models of geographic space. A 1995 paper titled “Naïve Geography” added a new dimension to the discipline, demonstrating that the commonsense view of the world could itself be a coherent and fruitful subject of scientific inquiry. Focusing on the particular domain of landforms, Mark pioneered the new field of ethno-physiography and is currently involved in a project to document and compare terms used by the Yindjibarndi and Navajo cultures to describe natural elements of the landscape.

An important aspect of Mark’s career has been his talent for facilitating cross-disciplinary collaboration through the organization of workshops, conferences, centers, and funded projects. In 1988, he was a member of the team that established the National Center for Geographic Information and Analysis (NCGIA), and he became director of the Buffalo NCGIA site in 1995. Mark was instrumental in the founding of the UCGIS in 1991 and served as one of its first presidents. Under his guidance, the Las Navas workshop spawned the highly successful ongoing Conference on Spatial Information Theory (COSIT) series. He was also program cochair of the first two GIScience conferences in 2000 and 2002. Perhaps his biggest success, however, was the establishment in 2000 of the first and only National Science Foundation Integrative Graduate Education and Research Traineeship (NSF IGERT) program in GIScience, which to date has funded 62 PhD students in seven disciplines.

Befitting his academic interest in natural kinds, Mark is also an avid birder, with a lifetime count of more than 2,700 species. In 1980, he broke the single-year Canadian birding record with 417 species.

MARKET-BASED ENVIRONMENTAL REGULATION

Market-based environmental regulation involves the use of one or more economic policy instruments by government agencies to regulate the environment. Such regulation is enacted as a means to an end—usually incentives to cost-effectively control air, water, or land pollution—though similar policies have been enacted for other purposes. These include payments for ecosystem services and controlling overfishing. Sometimes such market-based environmental regulation is considered neoliberal and is strongly promoted by free-market advocates, but in most

cases, these programs are instituted to maximize the cost-effectiveness of government action. This form of regulation has increased in popularity around the world following the success of the U.S. Environmental Protection Agency's Acid Rain Control Program, which began in the early 1990s. The main categories of market-based environmental regulations are environmental charges/taxes, tradable permits, and payments for environmental services. This entry addresses each of these in turn.

Environmental Charge/Tax Systems

Economists call environmental pollution an *externality*, or a social cost external to market transactions. The English economist Arthur Pigou proposed in 1912 that such market "failures" should be internalized by government taxation. Yet environmental charges and pollution taxes have had very limited application to date. One municipal system growing in popularity is to charge households or businesses for solid-waste disposal in proportion to the amount of waste generated, the so-called pay-as-you-throw or unit-pricing policy. A pollution tax was enacted under the Superfund Program created by the U.S. Comprehensive Environmental Response, Compensation & Liability Act of 1980, designed to clean up high-priority hazardous-waste dumps. This program created an excise tax on chemicals and petroleum companies, though it was rescinded in 1996. A few European countries have had experience with modest pollution taxes, including the Netherlands, France, and Denmark, and carbon or climate change taxes exist in Sweden, Finland, Norway, the Netherlands, the United Kingdom, and Quebec.

A more successful environmental charge program in the United States has been deposit refund systems, which have been enacted in 11 states for specified beverage containers and 12 states for automobile batteries. Deposit refund systems for beverage containers also exist in nine European countries, Canada, Israel, Japan, South Korea, Taiwan, India, Kiribati, Micronesia, and South Australia. Germany has a deposit refund system for car batteries, refundable deposits on beverage containers since May 2006 under the Green Dot Program, and broader "take back" packaging

requirements for industry to encourage recycling (funded by a license fee levied on the producer).

Tradable Permits

Emissions trading systems were based on the ideas of the economist Ronald Coase, who won the Nobel Prize in Economics in 1991. They were, however, not operationalized until their application by the U.S. Environmental Protection Agency in the mid 1970s. The idea is to provide flexibility for pollution sources to reduce their emissions by allowing trading among firms with different abatement costs. Two basic program models exist: One approach "offsets" emissions on a case-by-case basis, and the other approach allows trading among a large number of sources, with a cap placed on total systemwide emissions of a specific type.

Several applications of emissions trading have been for air pollution control, often by 50% or more. The focus has typically been on emissions from electric power plants. Most of these programs were developed in the United States, such as the national Acid Rain Program's sulfur dioxide (SO_2) allowance market, nitrogen oxide (NO_x) allowance trading in the Eastern United States, volatile organic compound trading in Chicago, and the Regional Clean Air Incentives Market for NO_x and SO_2 in Southern California. The Acid Rain (control) Program is considered a notable success. Greenhouse gas trading between nations is encouraged by the Kyoto Protocol. The European Union (EU) Emissions Trading System was implemented for this purpose in 2005, which covers nearly half of the region's emissions. Many of these programs allow for emissions "banking," whereby excess emission reductions made in one year can be used to meet future emission targets.

Tradable permit systems have also been applied to water. These include effluent trading in watersheds, wetlands mitigation banking (United States), water markets (Australia, Chile, South Africa, and the western United States), and individual transferable quotas fisheries management (New Zealand, Australia, Iceland, Canada, and the United States). Serious problems have beset these programs, with fisheries management being the most successful.

Payments for Environmental Services

Payments for environmental services (PES) are voluntary transactions for well-defined environmental services between one or more users or buyers, such as government, an international agency, or nongovernmental group, and sellers, usually private landholders. This phenomenon is another case where externalities may, under certain conditions, be overcome through private negotiation between the affected parties à la Coase. While strictly speaking not a form of regulation, PES usually requires government participation or sanction. These programs make the most sense when ecosystems are mismanaged because many of their benefits are externalities from the perspective of ecosystem managers. Examples include hydrological, watershed, and biodiversity services; soil and land conservation; landscape quality maintenance and enhancement; eradication of invasive plants; reforestation and forest conservation; and carbon sequestration. PES programs have been applied in developed countries such as the United States, the United Kingdom, and Australia and developing countries in Central and South America, South Africa, and China.

Criticisms

Several criticisms have been leveled at market-based environmental regulations, especially emissions trading and pollution taxes. One criticism is that these instruments are tools of neoliberal economic policy that serve class interests, sanction the right to pollute, and in the international context are neocolonial. Emissions trading systems have also been accused of promoting environmental injustice, since domestic programs such as SO₂ or NO_x trading can in theory result in greater geographic concentrations of emissions than if there were no trading. Questions have also been raised about the effects of international trading of greenhouse gases on developing countries, which may be enticed to sell opportunities for low-cost emission reductions to richer nations or their industries. These concerns notwithstanding, the popularity of market-based environmental regulations can be expected to increase around the world.

MARSH, GEORGE PERKINS (1801–1882)

George Perkins Marsh was a polymath, scholar, and diplomat. He was a well-known scholar in North America in the mid 1800s, published several notable works on the origins and history of the English language, and had an extensive knowledge of 20 languages. It is ironic, therefore, that he is best remembered for his seminal work *Man and Nature; or, Physical Geography as Modified by Human Action*, since he had no formal training in physical geography or ecology. Drawing on his keen observations growing up in Vermont and his subsequent travels in the Middle East, Marsh was the first to demonstrate that human activities have extensive, adverse impacts on the physical environment. Thus, Marsh is considered by many to be the first environmentalist.

Marsh was born in Woodstock, Vermont, in 1801. He was the fifth child of Charles Marsh, a district attorney under John Adams. George was a voracious, early reader, but he suffered an eye affliction when he was 8 years old that plagued him for the rest of his life. As a result, he developed a prodigious memory and an abiding love of the outdoors. Marsh pursued a variety of careers with varying degrees of success, including teacher, lawyer, editor, farmer, politician, and diplomat. In 1825, he established a law practice in Burlington, Vermont, which gave him an entrée into the world of politics. He served as a congressman in Washington, D.C. (1843–1849), where he helped establish the Smithsonian Institution. During his time as U.S. Minister to Turkey (1849–1854), he also traveled through Egypt and Palestine collecting specimens for the Smithsonian and noting evidence of human impacts on the environment. From 1861 until his death in 1882, he served as U.S. ambassador to Italy.

Man and Nature was published in 1864, but Marsh identified the underlying themes many years earlier in Vermont. He had observed that after the forests were cleared, springs dried up and excessive runoff after storms caused extensive erosion. Marsh was concerned not merely that humans were disturbing the balance of nature but that the cumulative damages so wrought would eventually harm society. His observations in Europe confirmed his theories but also indicated possible management solutions. Marsh was not a strict conservationist, but he blended a reverence for nature from transcendentalism with a good dose of Vermont practicality. He advocated taming nature for human needs through careful management.

Man and Nature was well received by scientists, policymakers, and the public, and it was instrumental in creating the national forest system in the United States and promoting improved forest management practices in the United States and Europe. *Man and Nature* remains a relevant and enduring classic.

MARXISM, GEOGRAPHY AND

Marxism—one of the world's most powerful and influential ideologies—has had an enormous social and intellectual impact on vast areas of the world, including the discipline of geography. Marxism is simultaneously a form of political economy, a moral theory of justice, a mode of historical perspective, and a platform for political action. It is clearly impossible to summarize this gigantic, complex, diverse, and occasionally contradictory body of work on Marxism in one essay; rather, following a sketch of Marxist political economy, this essay focuses on the multiple ways in which geographers have selectively appropriated Marxism to understand space. The encounter between Marxism and geography, it must be noted, was mutually transformative: As geography incorporated many central notions of Marxism, such as class, power, struggle, labor, and historical context, so too was Marxism also changed, becoming more explicitly spatial in focus.

Karl Marx and His Worldview

One of the most widely influential figures in world intellectual history, Marx studied Greek philosophy for his PhD at the University of Berlin in Germany, then moved to Paris in 1843, where he met his lifelong friend and coauthor, Friedrich Engels; in 1845 he moved to Brussels, then back to Paris in 1849, and then shifted to London in 1852, where he worked briefly as a journalist for the *New York Tribune*. He was active politically

in the International Workingmen's Association (also known as the First International) and wrote on behalf of workers' movements. Marx's major works include *Das Kapital* (three volumes), *The Communist Manifesto*, and *Grundrisse (Outline of a Critique of Political Economy)*. Marx and his ideas were clearly products of their times, that is, 19th-century Europe (especially Britain) amid the Industrial Revolution.

Marx was heavily influenced by three strains of European social thought, particularly German idealism, British political economy, and French utopian socialism. From Georg Hegel, whose works affected Marx enormously, he acquired a deep appreciation of dialectics, a sense of science as the holistic study of relations among phenomena, and a conception of the important role of human consciousness in structuring and changing social life. From French scholars such as Condorcet, Charles Fourier, and Comte de Saint-Simon, Marx incorporated the view that social relations were open, contingent, and subject to change. Later, however, Marx's early idealism is often held to have given way to a more materialist analysis, in which the forces and relations of production were preeminent. Finally, from British political economy, particularly the works of Adam Smith and David Ricardo, Marx learned the tools with which he dissected capitalism, including the labor theory of value.

There are multiple foundations of Marxist thought. Most centrally, Marxism is often equated with historical materialism, an attempt to make history into a science. Marxism is resolutely historical in focus, emphatically emphasizing that events, people, and ideas must always be situated within their historical context; thus, *when* things happen is critical to *how* they happen, for different societies produce different contexts. Departing radically from Hegel, who was known for his idealistic view of history, Marxism stresses that ideas originate from social and material circumstances, not vice versa; matter has primacy over consciousness. In effect, Marx "turned Hegel upon his head." Notably, historical materialism lacked a real sense of spatiality (i.e., there was, originally, no geographical materialism), and Marx himself said little about geography other than occasional references to the division between towns and the countryside.

Second, Marxism is usually interpreted to be structuralist in its focus, although this point is often debated. Structuralism as a formal philosophy emerged later than Marxism and had different roots (i.e., in linguistics). Nonetheless, Marxism typically (but not always) exhibits a structuralist ontology, that is, an understanding that what is real in the world is not merely what is observable but the relations among phenomena, which may not be immediately detected. In this sense, Marxism differs greatly from much Western social science, which is often empiricist or overly individualistic in focus (e.g., neoclassical economics). The holistic focus of structuralist ontology leads Marxism to view humans as inescapably *social* beings, with social origins and consequences, and they can never be understood simply as isolated individuals outside their historical context.

A third pillar of Marxism concerns the centrality of labor, a common notion among classical political economists. Labor (i.e., work and production) is privileged analytically: All societies must provide for themselves, and to do so, people must engage in organized systems of work. Through labor, people enter into social relations, reproduce society, materialize ideas, and change nature (as well as themselves). By privileging labor over other forms of social activity—as in Marx's distinction between the economic base and the political, legal, and cultural "superstructure"—Marxism made itself vulnerable to charges of economic determinism. The core of this view is the labor theory of value, which Marx acquired by reading Adam Smith: In this perspective, value emanates from the amount of *socially necessary* labor time that goes into the production of goods (not just one person's time but the minimum that a given historical configuration of technology and people can produce). Thus, value is produced at the workplace, not through exchange in the market (as in neoclassical economics), and the prices of goods will tend to gravitate toward the amount of labor embodied in their production.

Marx differentiated between use and exchange values: The former refer to the qualitative, subjective utility derived from goods (e.g., a house shelters a family and keeps them warm and safe), while exchange values refer to their market price

(e.g., a house can be bought and sold for a given amount). Because capitalism is the process of commodifying goods—turning them into objects bought and sold on the market, for a profit—labor too becomes a commodity, organized through labor markets. The key to understanding capitalism, for Marxists, is how the labor theory of value operates within the workplace: Because the use value of the worker to the capitalist exceeds his or her exchange value (i.e., wages and salaries), a surplus is inevitably generated. Workers thus produce all value but receive only the exchange value of their labor in return. Capitalists *must* pay workers less than the value of what they produce, or there would be no profit. The labor contract is, in this view, inherently and inescapably exploitative: There can be no such thing as a “fair wage,” for all profits are, by definition, theft from wages. Thus, Marx viewed labor markets as alienating, that is, separating workers from their capacity to generate value for themselves. Capitalists seek to increase profits by keeping wages low, but they also must increase purchasing power (wages) simultaneously. There is therefore a fundamental contradiction between production and consumption: In minimizing the costs of labor, capitalists also minimize the ability of workers to consume; workers are, in effect, forced to live on too little because they produce too much.

Arising from the organization of production is class, a foundational concept of Marxism. Indeed, Marx arguably was the first theorist to analyze society in class terms. Unlike popular definitions of class, which emphasize consumption and income, Marxist views of class begin with the relations of production, that is, whether one owns the capital, equipment, machinery, and other tools necessary to produce goods or whether one only can offer one's labor. Because the labor theory of value is trans-historical in nature, Marxism posits that all social systems other than “primitive communism” (i.e., hunting and gathering) have classes, including slavery, feudalism, capitalism, and socialism. The relations between classes are complex, contingent, and ever-changing. The primary classes of capitalism are capitalists (the bourgeoisie) and workers (the proletariat), although Marx did allow for other, smaller classes, such as peasants, the petit bourgeoisie (“middle class”), and the lumpen proletariat (the

impoverished, often homeless bottom rungs of society, which form a “reserve army of labor” that capitalists can use to lower wages as necessary). Class, it must be emphasized, is not simply an economic phenomenon but a political and cultural one too: In most societies, almost all members accept the ideas of the ruling class as “natural”; that is, ideology obfuscates the reality of class. Class divides become most visible during periods of crisis, and Marxism posited itself as a science of society, in contrast to bourgeois ideology or false consciousness. The contradictions between classes—class struggle—form the motor that drives history forward, leading to revolutionary changes by which one form of society gives way to another. Thus, Marx viewed history as the progression of various modes of production, giving Marxism a teleological sense of time, including the future as well as the past, which has been criticized for minimizing human agency.

Capitalism differs from other modes of production in that it must grow to survive. Under the relentless pressure of competition, firms must continually innovate; from this basic fact spring both the tremendous vitality of capitalism as well as its greatest weakness. The necessity to extract surplus value inexorably leads to conditions in which more is produced than can be consumed; that is, there is overaccumulation, which is built into the DNA of commodity production. Ultimately, this process leads to an excess supply, falling prices, and thus a tendency for the profit rate to decline. To combat the chronic problem of overproduction, capitalists must seek out markets on which to unload their excess output, leading capitalism to exhibit what Marx called a “wolf hunger” to expand, as with the European “Voyages of Discovery” in the 16th, 17th, and 18th centuries. Ultimately, Marx predicted, the crises of capitalism will intensify, immiserating the proletariat, leading it to realize its common humanity and replace the rule of capital with the rule of labor (socialism) and, eventually, a classless utopia of communism, where “true history” begins.

Marxism is much greater than Marx. In the 20th century, various kinds of Marxism arose in theory and in practice. Most common was the Stalinist version, which became dominant in the Soviet Union and its client states, as well as the Maoist variant in China. For some, Marx's

ideas are inspirational, sketching visions of a new world free of class and injustice; for others, Marxism was a dogmatic worldview that led to the horrors of the gulag and murderous totalitarian regimes. Academic variants of Marxism include the nonstructuralist version ("Western Marxism"), such as the Frankfurt School of the 1930s, led by Theodor Adorno, Max Horkheimer, and Herbert Marcuse, which focused on the role of culture (as well as its descendant, Jurgen Habermas); Antonio Gramsci's work on ideology; Rosa Luxemburg; Georg Lukacs; E. P. Thompson; and Walter Benjamin, who played a key role in analyzing representations and consumption in class-based terms. In the late 20th century, feminist Marxism added to the diversity of this worldview.

Marxism in Geography

The entry of Marxism into the discipline of geography may be held to begin during the turbulent decade of the 1960s, when radical geographers emphasized the need for social relevance. William Bunge, for example, led projects such as the Detroit Geographical Expeditions, and the journal *Antipode* was founded in 1969, followed by the Union of Socialist Geographers in 1974. The works of Henri Lefebvre were also inspirational, although they were not translated into English until the 1990s. With the adoption of Marxist ideas, space was increasingly viewed as a social and historical product for the first time, in contrast to its frozen, given status under both chorology and logical positivism, a shift that helped end the long rule of historicism in the social sciences and greatly elevated issues of spatiality in social thought.

The central figure in this transformation was David Harvey, who, in a series of works such as *Social Justice and City* (1973), *The Limits to Capital* (1982), and *Consciousness and the Urban Experience* (1985), initiated a systematic spatialization of Marx's magnum opus, *Capital*. The Marxification of geography was thus the spatialization of Marxism, in which historical-geographical materialism was transformed into a historical-geographical materialism. Harvey began the arduous task of charting the cycle of production from money to commodities and back to money form in

geographic terms, leading him to generate important notions such as the various circuits of capital, the spatial fix, and time-space compression.

Building on Harvey's contributions, Marxist geographers began to advance on several fronts. Many, such as Edward Soja, initiated a long-standing retheorization of the social and the spatial as simultaneously determinant arenas. A central theme that emerged throughout was uneven spatial development, that is, the inequalities between wealthy and impoverished regions that emerged as part of the changing capitalist division of labor. Contrary to neoclassical promises that spatial inequality would be mitigated by the movements of capital and labor, Marxists maintained that uneven development was a necessary, inescapable part of capitalism. This process was manifested as scales ranging from the urban (e.g., ghettos and suburbs) to the national (e.g., the Rust Belt and the Sunbelt in the United States, or Northern vs. Southern Britain) and the global (i.e., the schism between the developed and underdeveloped worlds).

Marxist international political economy, for example, theorized the possibilities of development in a world economy in which the rules were stacked against developing countries. Students of colonialism, such as James Blaut, offered devastating critiques of how the modern world economy came to be and the continued legacy of bias that privileges Western knowledge over that generated in other parts of the world. Dependency theorists, drawing on the works of Andre Gunder Frank, offered blistering critiques of modernization theory and its current variant, neoliberalism, to reveal that poverty does not simply "happen" but is a historical product, actively created, not simply given. Thus, via the process of underdevelopment, First World countries produced poverty in the Third World over 500 years of colonialism and contemporary neo-colonialism. Thus, underdevelopment is not simply a state but an active process. Wallersteinian world-systems theory extended this view to include a more sophisticated portrait of the dimensions of the global economy, including the political structure of the interstate system through its tripartite division into core, periphery, and semiperiphery. Such views have become the core of much political geography today, concerned as the subdiscipline is with globalization

and critical geopolitics in their various forms, as well as opposition to it.

Marxist geographers also reinvigorated the discipline's concerns with the state, which was, in social terms, not some unbiased, apolitical actor but an institution deeply linked to particular class interests. Moving beyond Marx's original assertion that the state amounted to little more than the "executive committee of the bourgeoisie" as well as neoclassical portrayals of the state as a parasite feeding off the largesse of the market, Marxists argued that it amounts to the instrument by which one class dominates another, or an arena of class conflict: Politics, in short, is class war by another means. In moderating the anarchic, self-destructive tendencies of the market, the state does what no single private entity can do (e.g., protect property rights, provide public goods and services, mitigate negative externalities). To facilitate the needs of capitalists, the state must legitimate itself in the eyes of its citizens, presenting a facade of representing the interests of the ruling class as the "public interest." The Marxist view of the state demolished fantasies of the unfettered free market and played a key role in the revival of political geography and urban political economy more broadly.

Marxist urban geography reveals cities as intertwined systems of production and reproduction, that is, as holistically integrated entities rather than just the summation of individual choices. The changing urban division of labor became a central object of inquiry in the works of scholars such as Allen Scott, Michael Storper, Richard Walker, and others, including the ways in which firms are integrated into networks of relations, and changing urban and global urban hierarchies. A bevy of urban topics fell under the Marxist gaze, such as the politics of urban land use, housing markets, suburbanization, ghettos and inner-city poverty, gentrification and the rent gap, and struggles over public space. Urban governance, ranging from regime and regulation theories to growth coalitions to the neoliberal state, received special attention.

Long sensitive to allegations that Marxism lacked an adequate theory on the subject, Marxist geography engaged in an intense debate, with humanistic geographers such as David Ley, over the relative weights to assign to structure and agency in social analysis. Some geographers

invoked overly determinist French scholars such as Louis Althusser, while others were inspired by nonstructuralist Marxist historians such as E. P. Thompson. The entry of Giddens's structuration theory in the 1980s effectively resolved this dilemma and led to the proliferation of social constructivism throughout the discipline. In essence, this matter forced Marxists to take seriously issues of ideology, culture, consciousness, everyday life, and social reproduction. Marxist cultural geographers such as Don Mitchell reframed culture not simply as a set of ideas but as a power relation tied to class interests. Feminist scholars effectively integrated Marxism with understandings of gender, injecting the first non-class-based forms of analysis into the discipline and opening the doors to identity theory. Others, such as Denis Cosgrove, offered insightful dissections of spatial representations ranging from landscape paintings to critical cartography to the history of the globe, drawing on Michel Foucault to assert that every form of spatial knowledge was also a claim to power. Many geographers influenced by Marxist notions of class, if not Marxists per se, analyzed the history of geography itself as a changing power/knowledge configuration.

Finally, Marxists even began retheorizing nature, and with it, human-nature interactions. Neil Smith famously argued in *Uneven Development* that the production of space was simultaneously the production of nature and that people and nature were always unified through labor, the conversion of material goods into social commodities. In this light, ostensible struggles of "people versus nature" are really struggles among social groups. Political ecology, with its attendant concerns for environmental justice, in many respects was an outgrowth of this line of thought, and it helped dethrone the simplistic, and often racist, Malthusianism, which blames the poor for their poverty. In environmental politics, for example, Michael Watts's work on African famines revealed that hunger is socially constructed through differential access to resources. Similarly, natural hazards are shown to be not "natural" at all but deeply entwined with class, race, and gender relations. In essence, Marxism helped denaturalize nature, revealing that it cannot be understood independently of society. The social construction of the nature perspective refutes

long-standing assumptions that nature is situated “outside” of human affairs, a primordial, unalterable “given.”

Marxism is not without its critics, many of whom continue to allege that it suffers from a debilitating economic determinism, an inadequate account of human agency, and teleological overtones. The end of the Cold War helped free academic Marxism from the horrors of the Soviet Union and inspired a new round of inquiry. Marxism has become so commonplace in human geography today that many practitioners scarcely call themselves Marxist. Marxism forced geographers to take historical context seriously; to understand spatial phenomena as social constructions, not simply as “given”; to appreciate the division of labor and the importance of work and labor; to understand how class figures in all social relations even as the ruling class keeps itself invisible via ideology; to address the ever-changing complexity of capitalism as an economic, political, and ideological system; to acknowledge the profound role of the state; to view ideas as inescapably linked to power interests, never as free floating in some abstract mental vacuum; and to gather around a common moral core grounded in justice, fairness, and opposition to sexism, racism, and other forms of social oppression. Marxism offers a comprehensive means to suture together many of the disparate topics that geographers study, in contrast to the common “test a million hypotheses” approach that tends to lapse into empiricism. As a moral philosophy, therefore, Marxism urges geographers to be critical, to point out how social and spatial relations could be better, and to never be satisfied with the status quo. To appreciate its impacts, one must view the many Marxist ideas that have insinuated themselves in political, economic, urban, cultural, and historical geography and via social constructivism more broadly into political ecology and even into contemporary retheorizations of cartography and geographic information systems. Thus, although the classical, 19th-century Marxism may have proved to be a failed historical project, contemporary Marxism—changing, adapting, modifying, borrowing, and contributing to other lines of thought—remains very much alive.

MASCULINITIES AND GEOGRAPHY

Masculinity is a concept that first and foremost implies that how men and women live and practice their lives is dependent on gender relations. Within these relations, masculinities take place and are expressed through practices that, according to Robert Connell, affect experience, personality, and culture. But the concept also has geographical implications as expressions of masculinities vary from place to place and influence place identities and local ongoing negotiations within existing gender relations. Masculinity cannot be understood as a singular or a static concept but will vary through space and time.

By focusing on the processes and relationships that define the variations among different masculinities, it is possible to reveal

geographical variations but also difference in status and hegemonic power. Spatial inequalities in the form of dualistic distinctions can, for example, turn into hegemonic versus deviant masculinities. Such a relationship is possible to find, for example, in the relations between urban and rural masculinities; masculinity as hegemonic differs with the geographical and social contexts.

The media are important actors in the construction of the differentiation of masculinities. A recent expression is in the great variety in Western European or Anglo American reality television series. One of the ideas behind shows such as the television reality series *Farmer Wants a Wife* is to essentialize rural identities and practices as well as demarcate the rural from the urban. Such relations are also expressed in people's daily activities, talk, and discourse. In the process of identifying oneself, one commits to certain, often geographically or culturally based, qualities while distancing oneself from others.

Geographers have taken the spatial implications of masculinities seriously and have focused on the importance of a contextual analysis. A trend that has been accentuated and developed recently is the increasing interest in how the relationship between masculinities and other identity-building dimensions such as class, sexuality, and "race" is constituted. In this understanding, places and spaces are merged with social processes. Thus, taking into account the relational character of identity construction and reconstruction helps avoid the common mistake in defining masculinity by using established divisions of behaviors as male or female.

The strengths of geography in defining and applying a concept such as masculinities are that (a) the discipline pays attention to existing geographical variations and (b) it illuminates the power relations inherent in the relationship between space and identity. By illuminating how space is used to build up discourses of differences, the reproductive as well as the transformative aspects of the concept of masculinities are exposed.

MASSEY, DOREEN (1944–)

One of contemporary geography's leading theoreticians, Doreen Massey has made numerous pioneering inroads in the analysis of space and place, including gender relations, globalization, and the nature of places. Massey is simultaneously an influential scholar in geographic thought; urban, economic, and political geography; feminism; and Third World development.

Born in Manchester and educated at the University of Pennsylvania and Oxford, Massey began her career at a London think tank, the Centre for Environmental Studies, from 1968 to 1980. In 1982, she became a professor at the Open University. She cofounded and edits *Soundings*, a journal of politics and culture. In 1982, she became a fellow of the British Academy, and in 1998, she was awarded the Prix Vautrin Lud (the "Nobel Prize of geography"). In addition to academic work, she is also a social activist and has also conducted extensive fieldwork in Nicaragua, Venezuela, and South Africa.

Much of her early work concerned the dynamics and implications of industrial restructuring and deindustrialization, particularly in peripheral places that attracted only industrial branch plants. British studies of deindustrialization indicated how it occurred differently in different places, with significant variations in the impacts. More broadly, no social process unfolds in the same way in different places. *Spatial Divisions of Labor*, which Massey published in 1984, was a critical book in the rejuvenation of economic geography. Massey examined changes in the spatial division of labor in Britain, unveiling how different localities experienced different "waves" of investment that powerfully shaped the local landscape, labor markets, gender relations, and

cultures. Over time, each region played different roles in the ever-changing national (and, increasingly, global) market. As successive “waves” were superimposed on one another, each region came to have a unique historical trajectory reflected in how various “rounds of production” were sedimented into the landscape. The resulting palimpsests both revitalized an older idea from cultural geography and allowed geography to accept local uniqueness in analytically rigorous terms by embedding local areas within broader notions of uneven spatial development. This line of thought led Massey’s contributions to play a major role in the revitalization of regional geography in the 1980s and 1990s. In this reading, space and place are not passive recipients of social change but actively contribute to their making.

Massey is also well known for her work on gender and feminist geographies. *Space, Place, and Gender*, published in 1994, broke new ground in pointing out the ways in which gender relations are spatially constructed. Broadly, she demonstrated how the home and social reproduction in general were as critical for capitalist accumulation as the workplace. For example, an influential essay titled “A Woman’s Place?” examined how changes in the British spatial division of labor reconfigured relations at home, leading at times to local patriarchal family structures and at times ones with relatively equalized gender roles.

Massey’s work on place was extended via poststructuralist theory into a notion of power geometries and relational space that called attention to the intertwined scales of the global, national, and local, refusing to see these as a simple hierarchy in which the global determines the local. Massey criticizes notions that maintain place as an island of stability in the constantly shifting oceans of capitalist change. Rather, she promotes a progressive sense of place that links places to other places, a view in which places constantly change, producing and receiving changes through their interactions with one another. A relational politics of place calls into question easy distinctions such as inside/outside, near/far, space/place, and global/local, artificial differentiations that are always embedded in each other and mutually constituted. In *For Space*, published in 2005, she argues passionately that

Cartesian conceptions of space as a passive surface inevitably de-emphasize the temporal flux that is always an inherent part of geographies and simultaneously create a false dichotomy between the local and the global. As an alternative, she suggests three maxims: (1) that space be seen as the product of interrelations, that is, of embedded social practices in which identities and human ties are co-constituted; (2) that space be understood as the sphere of multiple possibilities, that is, as a contingent simultaneity of heterogeneous historical trajectories; and (3) that space must be conceived as always under construction, in the process of forever being made, implying a continual openness to the future. Her latest book, *World City*, which appeared in 2007, undermines the notion that London and New York dominate the world’s financial markets; rather, all places are complicit in this process, and the volume asks readers to consider their role in producing and maintaining global geographies of responsibilities.

MASS WASTING

Mass wasting is a term for a wide variety of motions of rock, debris, earth, and organic matter that are moved downhill by gravity with various fluids entrained, such as water and air as well as ice. The concept of mass wasting is commonly supplanted by several other terms, such as *mass movement* or *slope failure*, and it also includes a tremendous diversity of things such as the various forms of creep, talus accumulation, flow of dry loess, burst of wet peat bogs, or block streams and rock glaciers as well. Classification of such diverse phenomena has been refined over the past century and a half, ultimately with emphasis on the types of material and types of movement, with a present-day consensus classification using rates of movement and the amounts and phase of the entrained H₂O system (water, ice, steam). The result is a matrix classification of mass-movement phenomena that enables understanding, although it is recognized that fine gradations of process type can occur in various continua between one form and another.

The types of material subject to mass wasting includes rock, as large masses or many smaller fragments; fine-grained earth, which is sand, silt, and clay; and fine organic matter, such as peat or humus in soil. Debris is a mixture of rock and

earth in various proportions. Types of motion in discrete landslides are falls, topples, slides, flows, and lateral spreads, whereas pervasive nondiscrete movements on slopes can include creep as well as isolated unit rock falls or slides that lead to accumulations of talus. Rates of motion range from the imperceptibly slow, where a few millimeters or centimeters a year occur, to hundreds of kilometers an hour, or even faster than the speed of sound, where lateral blasts from volcanoes impart exceptional velocities in certain cases. All phases of the H₂O system can be involved, from the merely ancillary presence of minor amounts of H₂O up to and including one phase or another of the H₂O as the primary motivating mechanism.

Falls of rock, debris, and earth (rock fall, debris fall, earth fall) from cliffs involve relatively simple accelerations through the air to a point of impact, at which point some further bouncing, rolling, and gliding of particles can occur to a certain extent. Topple failure occurs where a block of rock, debris, or earth rotates forward around a pivot zone at its base until it then tumbles over completely, usually breaking up in the process. Slides, such as the common rock slide, debris slide, or earth slide, can occur where rock debris or earth moves as one large block or breaks up into many separate units. They involve linear or translational slipping movements over inclined bedding planes or planar glide surfaces (as a glide block), or down curvilinear shear surfaces (as a slump block) with backward rotation. Flowing motions can be quite complex because there can be many laminar and turbulent actions in dry or wet media, where the particles move past each other in a variety of irregular motions that constitute distributed shear. For example, whole mountains can collapse internally under the force of gravity as a kind of rock flow or deep creep along many internal small shear planes until a ridge-top graben or ditch results in a sagging (sagging) failure with antislope scarps lower down as the mountain bulges outward. Or as sediment concentrations increase in mixtures of clastic particles of debris with water, forming a slurry that resembles wet concrete, various forms of rapid, wet, debris flow result. If the material is all fine grained, yet full of water, a mudflow occurs. If a dry mass of wind-blown dust or loess is shaken strongly by an earthquake, for example, all of the weak bonds between its particles may be ruptured,

and it can become a fluidized granular flow that is like loose talcum powder, as a loess flow. Or where a peat bog of plant-matter accumulation undergoes a torrential rainstorm, it may become super-saturated and break out as a bog burst. An earthflow results where fine-grained and damp clastic accumulations flow slowly downslope as viscous granular flows. On steep mountains where surficial soil layers, rock fragments, and vegetation are accelerated off the slopes in torrential rainstorms, a debris avalanche results. On the other hand, where a dry mass of rock fragments is detached from a steep mountain slope in what would normally be considered just a rockslide, if the acceleration is rapid enough, it may become a high-speed-flow *sturzstrom* landslide with a long runout zone.

Long-runout-zone slope failures occur where the ratio of fall height to runout length is generally less than about 0.6. This implies that the coefficient of friction between the flowing mass and the substrate is somehow reduced. These unusual *sturzstroms* were first thought to have been energized by trapped or entrained air that might somehow have kept the particles from interacting with the substrate and thereby have reduced friction. It was thought also that perhaps they formed a kind of wing shape or airfoil vacuum kept aloft like an airplane or were fluidized by moving air squeezing between particles, until such features were observed on the airless moon. Other explanations included mechanical dilation caused by strong vibration in motion and grain separation caused by acoustic vibration or sheer noise. Most recently, it has been recognized that rapid motion causes much frictional heat, which in turn converts any water into steam whose pressure will reduce friction. Indeed, a number of large *sturzstroms*, or rockslides, in the Himalayas and the Alps are now known to have melted glass “frictionites” in shear planes at their base. Finally, in some instances where blocks of glacial ice are also caught up in the moving masses, there may be a component of frictional reduction through incorporation of ice water mixtures in some fashion.

Lateral spreads or “quick-clay” failures are a special class of mass movement that incorporate unusual sliding and flowing motions so much that they can be quite dangerous and so are deserving of special attention. These forms of slope failure are caused where past continental glaciers first

depressed the crust isostatically into the sea, where they deposited their finely ground rock flours from abrasion of the bedrock. These small clay particles settled to the shallow sea bottom and collected as an aggregate of particles in a card-house matrix held together by ions of salt, where the positive sodium on one particle was attracted to the negative chlorine on another. Then, in postglacial times, with isostatic rebound of the mass up out of the sea, the fresh groundwater on the land would flush out the salt and leave behind an apparently stable but actually quite weak mass of wet quick-clay capable, when disturbed by constructional vibrations or other similar circumstances, of conversion or remolding from solid ground into a wet, soupy mass.

The role of water as a primary motivating agent in mass wasting or mass movement is well known, and if there is no preexisting slip surface to lubricate or make slippery, then some other aspects of the water must be responsible for the movement. Instead, what we find are a number of other important aspects, especially that water added to a slope has tremendous weight or load that can exceed the shear strength of the slope so that failure results. In addition, water can dissolve internal cements and thereby reduce cohesion, or it can produce hydrostatic pore-water pressure or seepage pressures underground. Similarly, saturation of sediments destroys capillary tension that can hold moist material together, or clays can swell as water is added, and freeze and thaw of slopes can disrupt materials and cause movement.

Talus is a form of one-by-one accumulation of rock fragments at slope bases where isolated rock units are pried off cliffs by the action of freeze and thaw and other minor disruptive processes. The rock particles bounce and roll downhill, sorted in part as a function of size and momentum, until they come to rest at the angle of repose, which is generally between 30° and 40°, depending on the size, with the coarser particles generally forming steeper slopes. Active talus is still in the process of being formed by additional small rock falls and rockslides, whereas inactive talus may have a vegetation cover slowly colonizing it.

Soil creep on slopes is a form of mass wasting that occurs all over the world yet is hardly noticed by most people. Fence posts, gravestones, and electric power line poles are tilted and displaced,

Mount Rainier National Park, Washington. The protalus rampart on the north side of Sunrise Ridge is separated from the partly vegetated talus on the left by a depression 5 to 6 ft. deep and 20 to 30 ft. wide. A thick, wedge-shaped snowbank blanketed the talus and the depression when the arcuate rampart was formed.

Source: U.S. Geological Survey.

retaining walls bowed out, and roads moved, all slowly and imperceptibly until the damage is done. Effectively, what happens is that a number of minor processes combine to move soil particles downhill in a series of uncoordinated but overall, in aggregate, quite pervasive small motions that collectively move enormous amounts of material. For example, expansion and contraction of soil particles on a slope occurs through wetting and drying, heating and cooling, and freeze and thaw. In any expansion part of the cycle, the slope materials move outward perpendicular to the slope, but in the return contraction, they tend to withdraw downward with gravity rather than back the way they came. The result is a ratcheting motion of out and down repeated over and over so that in aggregate everything is pulled downslope over time. Similarly, many other minor little processes move particles downslope; plant roots push a little more easily downslope than upslope against gravity, animals throw dirt from their burrows preferentially

downhill, and when the unused burrows or root cavities collapse, they do so downward. Any animals that walk on a hillslope have weight that pushes the soil downward a bit. Trees commonly have curved trunks on hillslopes that are often cited as evidence of soil creep that has pulled them into that curve, but instead, in a mix-up of cause and effect, it is not actually soil creep that produces the curve but rather creep of snow downhill against the tree that deforms it. In fact, this snow-creep force can also be transmitted into the soil through the roots and help cause the soil creep rather than be the result of it.

Creep of small protalus lobes and large rock glaciers in high-altitude and high-latitude environments is another form of mass wasting or mass movement that takes place where accumulations of rock fragments at the bases of cliffs become mobilized by creep of their internal ice cements or ice cores so that the features move forward as ever-increasing large lobate forms with transverse ridges

and furrows on their gently sloping tops and steep fronts at the angle of repose on their leading edge.

Gelifluction (*solifluction* in the older literature) is the mass-wasting process typical of permafrost environments, where the active summer thaw layer above the permanently frozen ground beneath becomes saturated with water that cannot percolate further downward and instead piles up in the soil to saturate it and cause instability. The combination of water-saturated soil on slopes above the permafrost, coupled with strong freeze and thaw in the soils, results in gelifluction lobes that move slowly downslope.

Other minor forms of mass wasting on slopes include blockstreams, which are thin masses of rock fragments that have been moved downhill, probably as a variation of a gelifluction process. Ploughing blocks on slopes move in a similar fashion, having to do with progressive freeze and thaw, probably because rocks lose their heat more quickly than the surrounding soils, so they freeze earlier to form ice crystals at their bases, which may help in their motion.

All forms of mass wasting or mass movement, whether they are landslides bounded by discrete shear surfaces or the diffuse results of unbounded creep, can result in deposits of unsorted, unstratified mixtures of multiple sizes of rock particles and organic matter. Such masses of sediment are considered to be *colluvium*, which is a nonspecific, generic term that can be applied. Commonly, because of the great diversity of forms of mass wasting, it can be quite difficult for nonspecialists to recognize the different types. Use of the term *colluvium* is, however, a safe way to classify an instance of mass wasting until more analytical studies can be performed.

MATHER, JOHN RUSSELL (1923–2003)

John Russell (“Russ”) Mather was an accomplished geographical climatologist whose career spanned the second half of the 20th century. Mather’s work is relevant because it helped establish the climatic water budget and the linkages between climate and water resources as major themes within modern climate science and geography. This entry recalls Mather’s work at the Laboratory of Climatology in New Jersey and at the University of Delaware (UD). His contributions to American geography—especially to the Association of American Geographers (AAG) and the American Geographical Society (AGS)—are summarized as well.

Mather was born in Boston, Massachusetts, on October 9, 1923. He began his career in 1948 at the Laboratory of Climatology—after completing his BS and MS degrees in meteorology at MIT—and worked there full-time until 1961. He simultaneously pursued his PhD in geography at Johns Hopkins University, completing it in 1951. Mather’s efforts at the laboratory were invested primarily in the climatic water budget, especially in its practical applications. Much of modern water-budget climatology was forged by Mather and his colleagues at the laboratory. Following the death of C. W. Thornthwaite in 1963, Mather became president and director of the C. W. Thornthwaite Associates Laboratory of Climatology, a post he retained until 1972.

Mather’s desire to teach—along with his ambivalence toward measurement work—moved

him to leave the Laboratory and join the faculty of UD in 1961. (He retired from UD in 2000.) In 1966, Mather became the first chair of the new UD Geography Department and began laying a foundation for its current programs, especially within climatology; his role in this is among his greatest achievements. Mather was the major advisor for 6 PhD students (5 at UD) and 17 master's students. His first PhD student was Mel Marcus, who, like Mather, was elected president of the AAG. Of Mather's UD PhD students, only Johannes Feddema now leads an academic life—at the University of Kansas.

Mather's enduring interest in the climatic water budget is evident in the overwhelming majority of his publications. He produced more than 25 journal articles and 60 monographs, and he published five important books. The books deal with applied climatology, water-budget analysis, water resources, American and Soviet geographers' contributions to global-change research, and, finally, the many contributions of C. W. Thornthwaite, Mather's mentor.

Mather held prestigious posts and received notable awards. He was elected president of the AAG in the early 1990s, and he received both the AAG and the AAG Climate Specialty Group Lifetime Achievement Awards in the late 1990s. Mather additionally served as secretary of the AGS and was honored with its Charles P. Daly Medal for distinguished service. He also was elected fellow of the American Association for the Advancement of Science in 1989. He died in Avondale, Pennsylvania, on January 3, 2003.

MAURY, MATTHEW FONTAINE (1806–1873)

Matthew Fontaine Maury is remembered today as the father of oceanography. During his lifetime, however, Maury identified himself with geography. In 1855, 30 years into his U.S. Navy career, the self-taught Maury pulled together the work he (and others) had done on Earth's oceans and atmosphere and published *The Physical Geography of the Sea*, a book that went through eight editions (reprinted into the 1930s) and was translated into six languages. Its title was posited by Alexander von Humboldt, who lauded Maury's scientific research. Oceanography came into vogue only after the HMS *Challenger* expedition (1872–1876), which had the effect of outmoding almost everything Maury had written. The most enduring contribution of *The Physical Geography of the Sea* was Maury's "Diagram of the Winds," which became a standard inclusion (with modification of the polar winds) in geography textbooks thereafter. Maury is also remembered for his pioneering work in the mapping sciences, particularly his charts of ocean surface temperatures, global ocean currents, the distribution of whales, and the "telegraphic plateau" between North America and Europe.

Maury was born on January 14, 1806, not far from Fredericksburg, Virginia, into a devoutly religious family, a fact reflected in the teleological orientation of his scientific writings. He saw divine purpose behind the order of nature and is therefore a transitional figure in the history of modern science. His inability to keep religion and science separate, combined with his over-generalizations and glib explanations of process, led to some stern criticism in the scientific community. Commercial interests, foreign governments, and the educated public, however, heaped kudos on him for applying science to practical problem solving at sea. As the first superintendent of what is today the Naval Observatory, Maury mined a trove of sailing logs and other records deposited in Washington, D.C., by ships' captains since the Revolutionary War. He used these data to prepare his continuously updated Wind and Current Charts, which made their first appearance in 1847 during the "golden age of

sail.” By recommending “tracks in the sea,” Maury’s research effected a revolutionary reduction in sailing time. By 1855, using Maury’s sailing directions, it took a clipper only 133 days to make the journey from New York to San Francisco; a decade earlier, it had taken 180 days. Maury’s charts were made available to foreign fleets; in return, he asked for copies of the captains’ sailing logs—more data for refining his advice to mariners.

Maury resigned his commission in the U.S. Navy in 1861, when Virginia joined the Confederate States of America. At the end of the Civil War, he moved to Mexico, then England, where he began writing a series of geography textbooks for schools. In 1868, he returned to the United States to take a professorship at Virginia Military Institute, where he undertook a physical survey of Virginia, revised his textbook on *Physical Geography*, and advocated for “agricultural meteorology.” He died in Lexington on February 1, 1873. His monument in Richmond proclaims him a “pathfinder of the seas.” An obituary in the *New York Herald* called him a “distinguished physical geographer.”

MCKNIGHT, TOM L. (1928–2004)

Tom Lee McKnight was an influential geographer, educator, and college textbook author. In a professional teaching career that spanned nearly

40 years, he wrote widely adopted textbooks on physical and regional geography and worked with college and K–12 teachers across the United States to expand and improve geography education.

McKnight was born in Dallas, Texas, on October 8, 1928. He was introduced to geography by Edwin J. Foscue at Southern Methodist University, where he graduated with a bachelor’s degree in geology and a minor in geography in 1949. He finished his master’s degree in geography at the University of Colorado in 1951 and his PhD in geography at the University of Wisconsin in 1955. In 1956, McKnight was hired by the Department of Geography at the University of California, Los Angeles (UCLA), where he served as department chair from 1978 to 1983.

Throughout his career, McKnight traveled widely, specializing in the geographies of Australasia and North America. He helped establish the University of California Education Abroad Program in Australia and served as its first director from 1984 to 1985. In addition to teaching at UCLA, he had appointments as a visiting professor at nine American, three Australian, and three Canadian universities.

McKnight was a vigorous advocate for the discipline of geography. He helped develop the Community College/UCLA Geographic Alliance. This organization of educators was a model for the National Geographic Society Geographic Alliances that eventually spread throughout the United States and Canada. McKnight’s textbook-writing career began in 1961, when he was asked to join Edwin Foscue and Langdon White as coauthor for *Regional Geography of Anglo-America*. McKnight became sole author of this textbook by its fifth edition, then retitled *The Regional Geography of the United States and Canada*.

In 1984, the first edition of his popular *Physical Geography: A Landscape Appreciation* was published. Well illustrated and written in an accessible style with strong emphasis on the integration of the four “spheres” of physical geography—atmosphere, hydrosphere, biosphere, and lithosphere—it quickly became one of the most widely used, and most influential, college-level physical geography textbooks. In 2002, this book was given the *McGuffey Award* by the Text and Academic Authors Association in recognition of its enduring excellence.

Among his other textbooks are *World Economic Geography*, with Langdon White and Paul Griffin (1964); *Australia's Corner of the World: A Geographic Summation* (1970); *Essentials of Physical Geography* (1992); *Introduction to Geography*, with Edward Bergman (1993); and *Oceania: The Geography of Australia, New Zealand, and the Pacific Islands* (1995).

His many awards and honors include a Fulbright and an American Philosophical Society grant for research in Australia, the California Geographical Society's Outstanding Educator Award in 1988, and the Australia-International Medal from the Institute of Australian Geographers in 2001.

Tom McKnight died on February 16, 2004, at the age of 75.

MEDIA AND GEOGRAPHY

How and why geographers engage with media is inherently tied to questions of what media are and do. The term *media* itself is ambiguous: dictionary.com defines the singular form *medium* as “an intervening agency, means, or instrument,” and the term was first applied to printed newspapers more than two centuries ago. Since the early 20th century, the usage of the term as a singular collective noun began to be popularized and its application expanded. Following this general meaning and expanded usage, an intersection of media with geography can be understood as an intimate and inextricable part of the geographic discipline. From long-standing traditions of cartographic creation and analysis to humanist explorations of art and literature to critical, feminist, and poststructuralist engagements with film and multimedia, different media forms have proved both informative and revealing for

geographers working through different modes of theoretical and methodological encounter.

It is generally agreed that media in their different forms—such as film, music, newspapers, comic books, video games, animation—are produced and consumed in historically specific and carefully constructed ways and that many factors combine to frame how meaning and expression are generated. Thus, media cannot be engaged in isolation but rather must be linked in multiple and complex ways to other forms of material evidence and theoretical engagement. Current streams of media geography largely take a critical approach to different media types, moving beyond understandings of media as visual or naive reflections of the “real” world or as materializations of the preestablished intentionality of their maker to understandings of media as discrete moments in the production and circulation of cultural meaning or expression. Importantly, this point is not to limit media to technologies of meaning (re)construction but also to understand media as objects of information transfer and creation wherein media themselves may be understood as differentiating forces of communication, social contestation, or affective and intellectual transformation. Media geography, then, explores broad questions of material production, cultural meaning, and bodily affects and percepts in relation to the practices and processes by which geographical information is gathered, geographical facts are ordered, and imaginative geographies are created. The differences present in how these questions are engaged with are not so much a matter of different understandings of media themselves as of what different forms and types of media do or can do.

Friedrich Kittler believes that media determine human situations, while Marshall McLuhan's famous phrase “The medium is the message” is also applicable to the study of media geography. Later critical geographers argue that media hold powerful transformative potential because people use cultural representations to create social relationships and to define space. These observations concerning media underscore differing insights into the meaning of information, the material importance of media, and how forces of technical expression may both positively and negatively

influence or affect our lives. What the observations share are their important implications for an understanding of media today, particularly within the context of geography.

Media geography often takes different media forms that are presented as natural, universal, or true and analyzes them to reveal how alternative geographic narratives may be visible. For instance, recent research in media geography has explored and explained the bond between media culture and nationalism or gender relations, providing insights into the motivations of media producers to prioritize time and history over space and geography by enmeshing the media consumer in systems of visibility and normalization. To critically engage media landscapes, then, it is important to understand that their places and spaces are never neutral.

Doreen Massey's early work conceptualized space as created by social relations, full of power and symbolism and containing a complex web of relations. Just how spatial-social power structures are involved in the transformation of these geographies may both reflect and serve as virtual and concrete responses to contested spaces/places. Geographic media studies help uncover the political interests underlying the production of cultural representations by presenting geographies through which to study these issues and their transparencies: As a number of recent works have noted, artistic quality often matters less than the role of the consumers and their attempts to resist and subvert the reinforcement of gender, sexual, and/or racial stereotypes. Media geography thus also promotes the active role of the consumer—understanding the relations of creative production comes first, followed by the different perceptions it may guide. Researchers can thus be exposed to the interconnections between private and public, especially private meanings and their role in sustaining and/or transforming personal and social forces such as memory and remembrance.

In addition to the readily apparent and tangible roles media forms offer to geographic exploration and analysis, it is also important to explicitly “place” media within different geographic discourses both contextually *and* methodologically if their full geographic power is to be realized. John Thornes advocates for media literacy in geography

because of the discipline's great visual legacy and suggests that there is a certain geographic clarity that can be derived from the study of media representation or expression. However, geographers should be open to moving beyond more orthodox notions of the “visual” to include the different sensory forces often present in media, such as sound images. Recent work within the discipline has stressed this point.

In an important article, Daniel Sui explored how visual geographic metaphors are being replaced by more evocative aural metaphors more common to electronic communication media, resulting in a reconfiguration of geographic discourse in the late 20th century. Sui made the connection that sight and sound are interconnected in many ways and should therefore be more fully appreciated for what they can bring to the exploration of geographic phenomena. Because of this, Sui emphasized how geography will become intellectually handicapped if the discipline confines itself to a single set of metaphors. This view led to positivist, realist, postmodern, feminist, and anarchist approaches to visualization that expanded the differing conceptualizations of visibility and defined media as inherently geovisual (in a broad sense of the term), while also understanding that there is an equally inherent geographical specificity to each media event. However, what this specificity is may always be open to contestation and negotiation. Clarity about what media are and do, then, requires an acknowledgement of both affective *and* kinetic aspects of media to account for epistemological and ontological differences in how media are understood, encountered, and engaged.

Media may change meaning as the environment in and through which they are consumed and engaged with transforms. Therefore, the function of their characteristics in relation to social processes can be understood as the purveyor of a specific relationship to the body and the imagination. The inherent characteristics located within media forms can instill emotional comfort or distancing, confinement or intimacy, hope or threat. Recent work has also found that media are a cognitive mode of understanding that can provide a “scientific” method for grasping the complexities of the postmodern world. Furthermore, new relationships within and between

various forms of “mixed media,” as interrelated sets of objects and texts, highlight exciting new forms of geographical analysis and bodily engagements with media and their role as both social network and agent.

There exists an affinity between the generic structures of media and the concerns of postmodernism that perhaps clarifies the necessary attention to the production and consumption of media, specifically how the body has been figured in postmodernism and cultural theory as a site of crisis. It is possible to gain important insights into geographical phenomena such as the city and landscape and into geographic technologies such as GIS (geographic information systems) and even video games and comic books through the use of different geographical theories and concepts working through the body. Such modes of exploration are helpful in understanding the production of media space and the creation of a *spectorial topoanalysis*, Giuliana Bruno’s term for the spaces of a spectator’s engagement with space through the experience of film. Popular media can be placed into a theoretical context bounded by semiotics, theories of ideology and subjectivity, ideas of affective concept and thought creation, and theories of self and identity. There are different semiotic complexities to media texts (including literal and symbolic meanings), leading us to conclude that media and human understandings of the world are inseparable from the bodily imagination and that spectorial subjectivity is entangled within a predisposed and socially influenced embodied gaze.

One can, of course, view media as a text, and the use of the textual metaphor runs deep in media geography theory. Various works discuss the concerns of qualitative methodology related to how the world is viewed, experienced, and constructed by social actors, while also stressing the importance of systems of meaning to any qualitative textual analysis. This methodology provides access to the motives, aspirations, and power relationships that account for how places, people, and events are made and represented. An interpretation of texts, which can include landscapes, archival materials, maps, literature, or visual images—all forms of media—is one of many ways of qualitatively engaging with different media forms or types.

In these explorations of the intersections between geography and media representations, media geographers may focus on a single static photograph—as in Susan Sontag’s claims that photographic images provide most of the knowledge people have about the look of the past and the reach of the present. Edward Said also saw the importance of “fictional” texts to the production of geographical knowledge, particularly how the interpretation of texts can provide insights into the ordering of society and space. Texts may be understood as culturally coded and may contain clues to the political, social, and economic circumstances of the society that produces them. This view, in turn, results in what some geographers see as a larger and a more critical engagement between cartography and social theory that may bring about a better understanding of how media can be best used within the discipline of geography.

If the geographical imagination can be conceived broadly to include those practices and processes by which we both situate and create ourselves and in which our selves are situated and created in space and time, then media participate in at least three fundamental ways: (1) in empirical practices of gathering factual information in visual and aural forms; (2) in cognitive processes of ordering information to produce knowledge of spaces/places, peoples, and events; and (3) in the affective and imaginative processes of visualizing the world beyond conventional experiences.

While media may be engaged from the perspective of agency and causality, narrative detail, circulation, or consumption and affect, media researchers are interested in focusing on the ways in which geographers might use media to allow technologies and critical geographies to intertwine in a useful discourse so that we might more fully understand the spaces, identities, and powers contained within the performances of particular media forms or representations and learn how to harness these powers. Using media to think geographically can illuminate issues far beyond the narrative content of media. The constructions and performances are central elements in ongoing and increasingly visual and aural encounters between diverse cultures, not to mention engagements with our own cultural productions and social relations of the past, present, and future. The spatiality of social

interaction is naturalized, and indeed neutralized, within the realistic appearance of media representations and is inscribed by sociopolitical relations of which media are simultaneously medium and product. Vision, for example, and thus its media manifestations, can be irrevocably tied to domains of knowledge, arrangements of social space, and lines of force and visibility. While this constitutes the cultural formations that make visual media possible, these forms of media cannot simply be reduced to signifiers of social forces and relations premised solely on models of *media theory* or to models of spectacle within politically based culture wars, as the controversies related to both Mel Gibson's *The Passion of the Christ* and *Apocalypse*, Michael Moore's *Fahrenheit 9/11*, and the Al Gore-narrated *An Inconvenient Truth* so aptly illustrate.

MEDICAL GEOGRAPHY

Medical geography, also known as health geography, is the application of geographical methods and techniques to the study of health. Research in medical geography has as wide a reach as research in the health sciences to address issues of disability, access to health care, parasitology, the spatial distribution of cancer cases, and the diffusion of diseases.

Although studies of human-environment interactions in relation to health are among the oldest recorded in medical research (e.g., Hippocrates), medical geography has gained particular prominence today as a way to better understand health beyond the confines of the human body, by examining health in local, regional, and global contexts. The way in which this is done ranges from post-modern Foucauldian critiques of the construction of mental health and the physical design of sanatoriums to the mapping of cancer rates across cities and states. While there are many approaches adopted within medical geography, three common theoretical views are described here: (1) human ecology, (2) the structuralist interpretation, and (3) critical approaches. Subsequently, common techniques, involving geographic information systems (GIS), spatial analysis, and remote sensing, are described as they relate to the field of medical geography.

Human Ecology

The human ecology approach to medical geography proposes an understanding of health that is integrative, concerning population, behavioral, and habitat characteristics of the state of individual health. Population factors affecting health include genes, gender, and age. Stages and differences in the life course of individuals are significant determinants of health status. However, of importance to the human ecology approach is the subjugated role of genetics, where behavior and habitat rank equivalently with demographic and genetic measures in understanding health. Behavioral factors integral to understanding health include belief systems, social networks and organization, and access to technology, broadly defined. Habitat components include

characteristics of the natural habitat, the built environment, and the social environment. Also important to the human ecology approach is the recognition that the factors that affect health operate at a variety of scales, microbiotic to global, and are mediated in a number of ways by social and natural environments.

The human ecology approach interweaves geography with numerous disciplines: ecology, population biology, genetics, demography, epidemiology, the social sciences, public administration and policy, urban and regional planning, and architecture and environmental design, as well as medicine and the health sciences. Rarely is it possible for research scientists to span the ecological approach with necessary attention to all its components; however, an appreciation for the larger interactions among individuals, across scales, and spanning time offers a quintessentially geographical grounding to the research.

The Structuralist Interpretation

Types and organizations of power structures have enormous implications for understanding inequities in health, vulnerabilities to disease, and lack of access to health care. A structuralist approach to health examines the ways in which power arrangements play out on individual health. Medical geographers have adapted this approach by helping to articulate and visualize the ways in which disempowerment is shown through inequities in health across space (across countries and within countries). For example, to critique economic indicators such as national income, health metrics, such as infant mortality rates and life expectancy, are increasingly used to understand development differently.

Critical Approaches

Critical approaches have done much to rethink the way in which we understand, or construct, notions of health and illness. Feminist methods have revealed the ways in which Western, biomedical approaches interfere with female conceptualizations of the body, in relation to the social and natural environment. Critical race studies have challenged the dichotomous and limited

view of race and ethnicity commonly used in design frames for medical experimentation and research. Furthermore, postmodern perspectives have also criticized how health care is operationalized, particularly in defining mental behaviors or forms of disability as problematic, in need of correction, observation, and remedy. Medical geographers have adapted critical approaches to study how localities and design manifest as evidence of power constructs.

GIS and Spatial Analysis

Though cartographic techniques have been used in the health sciences for many years, developments in GIS have led to the automated collection, distribution, and analysis of disease and measures of health. Health and behavioral surveillance systems are now also collecting geographic information (address information at a minimum or geographic coordinates—latitude and longitude), as are the agencies that collect vital records and statistics (birth certificates and death certificates) and agencies that conduct large-scale health interview surveys. A few countries, or localities, are now operating with real-time disease surveillance. The digitalization of health information offers many new opportunities to monitor and evaluate the distribution of disease. Simulations of disease outbreaks can be generated, and individual and ecological correlates of disease can be studied, using techniques such as multilevel modeling and hierarchical Bayesian approaches.

A variety of types of cluster analysis have been devised by geographers, many for health applications specifically, such as the Geographic Analysis Machine (GAM), space-time scan statistics, and Local Indicators of Spatial Analysis (LISA). Cluster analysis has been used widely in medicine and public health to identify hot spots, or areas where to target health care funding, in relation to sexually transmitted diseases and other contagious diseases, cancer mortalities, and vector-borne diseases (e.g., malaria, dengue fever, and Lyme disease). GIS and spatial analysis have also been used to study differences in access to health care, how neighborhood and urban design affect access to healthy food options, recreation, and walking as an alternative to automotive transportation, and inequities in exposure to toxic releases.

Health Applications of Remote Sensing

In addition to the mapping and analysis of disease patterns with GIS, medical geographers are using remote sensing, such as satellite imagery and aerial photography, to study the habitats of disease vectors, such as mosquitoes, ticks, or flies. This is done by classifying imagery associated with vegetation and examining vector habitats in proximity to the built environment. There is increasing interest in the health consequences of climate change on human populations that occur through intensification of human migration as well as the spreading of vector populations in response to warmer climate.

Future Directions

Future directions in the arena of medical geography involve the development of databases and analytical tools that better enable geographers and health professionals to study information about individuals that may change over both space and time. This will allow researchers to distinguish between differences in environmental exposures and changes in the social environment, which can affect health differently in different localities over the life course. In particular, the study of migration and health, which was very difficult before, is becoming more manageable. Other space-time survey data sets capture daily travel patterns, using armband GPS devices, which can be used to study urban land use patterns from the individual perspective, and study what those use patterns mean in terms of opportunity for healthy behaviors. Other research directions promise to investigate the impact of climate change on human health and how the impacts differ locally. HIV/AIDS and the social consequences of coping with HIV/AIDS (e.g., orphans and the decline in the productive labor force) continue to be on the forefront of the global public health agenda. Finally, medical geographers are studying how activities in the global political economy manifest locally and affect human health across borders. A few components of such research are sex work, the global drug trade, the global arms trade, and the growth of urban slums and borderlands, all of which are intimately linked with issues of global public health.

MEINIG, DONALD (1924–)

Until his retirement in 2004 as Maxwell Research Professor of Geography at Syracuse University, Donald W. Meinig was one of North America's most accomplished and productive historical geographers. A native of the Palouse region of eastern Washington State, Meinig received his MA (1950) and PhD (1953) from the University of Washington and taught at the University of Utah before joining the faculty of Syracuse University in 1959. During his long and distinguished career, Meinig produced a series of highly praised studies that provided new interpretations of the historical and cultural forces that shaped several distinct American regions, including the Northwest, Mormon country, the Southwest, and Texas.

Meinig devoted the last two decades of his professional career to a monumental four-volume series, *The Shaping of America: A Geographical Perspective on 500 Years of History*. This unprecedented achievement represents the most ambitious attempt ever by a geographer to bring the entire enterprise of discovery, conquest, settlement,

and development of the United States into a coherent conceptual framework.

Meinig's approach in this study is to portray America as a "gigantic geographic growth with a continually changing geographic character, structure, and system" (Volume 1, p. xv), with close attention to the varieties of peoples involved and the larger context of bordering societies. Throughout the series, he emphasizes the imperial dimensions of this enterprise and demonstrates that America was "created from a massive aggression against a long succession of peoples" (p. xviii). Throughout a narrative of more than 2,000 pages, Meinig employs several consistent basic principles that inform his approach: context, coverage, scale, structure, tension, and change (pp. xvi–xvii). He also examines the dynamic and changing nature of the spatial morphology of the United States using the concepts of core, domain, and sphere that he developed for earlier studies.

Unlike most professional geographers, Meinig does not claim to belong to a tradition or school of scholarship, and he feels that this lack of association gave him the freedom to move geography—historical geography in particular—in new directions. He has been particularly interested in elevating regional geography from the practice of merely listing categorized descriptions into something more artful and interesting to other disciplines. His method of doing this is to add history, context, interconnection, and constant flux to regional description, remaking it as interpretation and focusing on space, place, and change. To Meinig, geography has the potential to be art as well as science. To be a geographer is to see the world in a particular way, and to do geography is to express this view with language, diagrams, and maps full of movement and tension. Although few geographers have been as careful as Meinig in their use of language, fewer still have been as masterful in their use of maps and diagrams to enhance their interpretative narratives, to stress the dynamics of change, and to stimulate the geographical imagination.

Few works by geographers have received the attention and praise across disciplines that Meinig's work has inspired. Historians in particular have embraced his grand narrative for the scope of its monumental task and the explication of patterns that resulted from his approach. Nevertheless, he

has been criticized for privileging pattern at the expense of process and political and social forces at the expense of economic and environmental ones. Other critics have found his language to be, on the one hand, too carefully crafted for effect and, on the other, unscientific and imprecise.

Nevertheless, Meinig has brought to the writing of American historical geographies a wealth of fresh ideas and a high standard of literary and cartographic excellence. He stimulates the geographical imagination of readers with lucid prose that is challenging and yet free of jargon and with maps and diagrams that are equally fluid, readable, and vivid.

MENTAL MAPS

The term *mental map* refers to the cognitive representation of environmental information that a human being acquires through different (direct and indirect) sources. The term was first used by Edward Tolman in 1948 to refer to the mental representation of spatial layouts learned by rats to find food in a labyrinth. The term is synonymous with the terms *cognitive map* and *spatial mental representation*. The latter expression is a more neutral term offered in response to the criticism that the map metaphor is too restrictive and provides the incorrect impression that environmental information is indeed mentally stored in a maplike format. Nonetheless, the term *mental* or *cognitive map* is still widely used. The criticism and discussion of the map metaphor was particularly active in the second half of the 20th century, and alternative terms have been proposed, such as *spatial schemata*, *cognitive collage*, and *world graph*.

Mental maps are the result of a multimodal integration of various information sources. On the side of the cognitive agent, different sensory inputs contribute to the information that is stored about an environment. Visual information is the most prominent sensory channel, leading to abundant information about environments through direct experience. However, research has shown that environments are perceived and understood in diverse ways, not through visual perception alone. Besides other *exteroceptive senses* (i.e., senses that receive or respond to information from outside the body, e.g., smell, hearing, and balance), *proprioceptive information* (information about the internal state of the body) has been shown to contribute to understanding spatial environments. Proprioception and *vestibular* (balance) information, for example, play an important role in establishing an understanding of travelled distances and spatial environments, even in the absence of externally caused body movements such as those that occur when traveling by car or train. The multimodal origin of mental maps is supported further by the fact that they can be created in the complete absence of visual information by both sighted and visually impaired cognitive agents.

Mental maps are also created through the study of secondary sources. These sources can be in map format themselves, either as classic paper maps or digital tools, such as Google Earth (the most common Earth viewer), providing maplike information. Other secondary sources include texts (e.g., travel itineraries, movies) and verbal descriptions of spatial environments (e.g., route directions). In the latter case, the mostly qualitative verbal descriptions provide input for creating an often underspecified, sparse mental representation of a spatial environment that, when interacting with the environment, can guide spatial behavior.

Hence, it is important to bear in mind that mental representations of spatial environments are the result of a multimodal combination of sensory inputs and are not restricted to visual information alone. Furthermore, nonsensory sources such as maps, text, and verbal descriptions also contribute to the kind of information that is stored in a mental map.

Distortions in Mental Maps

One of the defining characteristics of mental maps is that they systematically represent certain aspects of the environment while neglecting others. This phenomenon is often referred to as distortions in mental maps. For example, distance, angle, and areal extent are not veridically represented in a mental map (a property that they indeed share with most cartographic maps). However, the selectiveness of cognitive agents regarding which aspects to represent in a mental map is an evolutionary necessity that should be seen as a positive adaptation to their environments rather than a limitation. To draw an analogy, mapmakers pursue a very similar goal by emphasizing some aspects and deemphasizing others to abstract a large, complex environment to the size of a map or to communicate only a particular characteristic of an environment. The selection criteria that humans employ are often more abstract (schematic) than the mapping rules in cartography. Additionally, the mental representation of environmental information is not constrained by a representational medium such as the two dimensions of paper maps; mental representations are not a map. This means that inconsistencies can be resolved more easily in mental maps and do not pose a representational problem.

The absence of selection strategies would lead to an information overflow in a cognitive agent that would slow down decision making dramatically. While we are seldom in danger from predators these days, the evolutionary roots are important to understand. This evolutionary adaption is what Andy Clark terms the “007 principle”: Evolved creatures will avoid storing information about environment in a costly way. They instead use the environment itself to contribute information and fill in the gaps (or details). Cognitive beings aim to know only as much as they need to know.

Much research has been devoted to revealing the aspects of environments that the human cognitive system is focusing on and that are used to simplify complex spatial relationships. It is important to understand that the inconsistencies in mental representations are often resolved by offloading information to the environment. This means that we do not need to mentally store every aspect of information about the environment, just those aspects that allow us to make the right decision (at least in most situations). An example is the tendency to orthogonalize intersections (see below) rather than mentally representing angle information properly. In almost all navigational situations in street networks, angular information is not relevant for successfully choosing the correct route (branch) to take at an intersection. The following are among the most prominent aspects of organizing spatial knowledge:

Cognitively Salient Elements of Environments. While landmarks are among the most researched elements that humans use to anchor spatial information, other elements are essential for organizing spatial information cognitively. The term *cognitively salient* has to be extended to mean not only visually salient objects but all structures that cognitive beings use to organize spatial knowledge. To this end, in 1960, Kevin Lynch identified the following five categories of structures used by cognitive beings to organize spatial knowledge: (1) landmarks (salient entities in the environment), (2) nodes (strategic places in the environment, such as street intersections), (3) paths (predominant elements in built environments that connect nodes and landmarks), (4) districts (area-like elements), and (5) edges (boundaries between areas).

Figure 1 Physical locations of San Diego and Reno are often different from those in mental maps.

Source: Robert Roth.

The Hierarchical Organization of Spatial Knowledge. In a classic experiment by Albert Stevens and Patty Coupe, participants had to indicate the direction from San Diego, California, to Reno, Nevada (tested against various other pairs of cities). Most participants judged Reno to be east of San Diego, while it actually is located to the west (see Figure 1). Stevens and Coupe were able to demonstrate with this experiment that the information that is represented on states (California is west of Nevada) is inherited by the cities within that state. Thus, because the information is hierarchically organized, an incorrect inference of the relative positions of Reno and San Diego is made (in this example).

Aligning Spatial Information. B. Tversky noted that one way to simplify directional information between entities in space is to align them with each other. A prominent example is the mental representation of North and South America along a primarily north-south axis. However, the actual

latitudes of the two continents are instead diagonally placed to each other. This effect can be observed for many entities located in space. On a smaller scale we find, for example, the following simplifications that are applied to street networks: the orthogonalization of street intersections, the straightening of curved paths, and the alignment of nonparallel streets.

Understanding the mental representation of spatial information (often referred to as a mental map) is a central research topic in and outside geography. The goal is to fundamentally understand how information about our environments is cognitively processed, stored, transformed, and communicated. Research on mental maps has led to several insights into how spatial information is cognitively structured. Revealing the principles that underlie human understanding of environments is important, as it allows for tailoring technical solutions to spatial problems (e.g., wayfinding or spatial decision making) using the strategies naturally used and understood by humans.

MERCATOR, GERARDUS (1512–1594)

Gerardus Mercator was a Flemish engraver and cartographer who lived during the so-called Age of Exploration, that is, the 16th century, when European capitalism and colonialism began their epochal period of global conquest, and his work both reflected and greatly enabled this expansion.

Born Gerhard Kremer, Mercator changed his name as a university student in Louvain, where he lived from 1530 to 1552. At an early age, he studied to be a priest at a monastic school in Her-togenbosch, where he learned calligraphy and Latin. In Louvain, he was trained in philosophy, surveying, scientific instruments, mathematics, astronomy, and geography, receiving his master's degree in 1532. He married in 1536 and eventually had six children. In 1544, he was jailed briefly under suspicion of heresy but released for lack of evidence. In 1552, he relocated to Duisberg, in what later became Germany, where he taught mathematics at the local gymnasium, or high school, until the cartographic workshop he founded acquired steady work under his long-time patron, the Duke of Cleves.

While his early talent lay in engraving, Mercator steadily moved from detailed maps of Flanders to globes to flat maps of the world, whose projections drew on his mathematical training. Some claim that Mercator coined the term *atlas*. In 1538, he published a double-cordiform (heart shaped) map of the world, the first to show two distinct continents in the Western Hemisphere; this map was lost but was eventually found in New York in 1878. In 1546, he produced a set of observational instruments for use in Charles V's campaigns. Thereafter, he took to producing a series of maps and globes, particularly concerning Europe. In 1578, he published a revised version of Ptolemy's classic, *Geography*, including 27 maps. A comprehensive global atlas begun in 1585 was completed and published by his sons in 1594, after Mercator's death.

Mercator is most famous, however, for his map projection, named after him, which he unveiled in 1569 with his *Nova et Aucta Orbis Terrae Descriptio ad Usum Navigatium Emendate* (New and Augmented Description of the Earth Designed

Figure 1 Mercator's projection of the world famously allowed easy lines of constant compass bearing but distorted areas at a great distance from the equator.

Source: Author.

for Purposes of Navigation). It is a cylindrical projection with no distortion at the equator. Unlike earlier maps, this one employed a graticule of latitude and longitude lines that did not converge at the poles. Simon Winchester calls it “an adroitly contrived confection of secants and cosines; it was neat, tidy and hugely popular; and it was turned into charts that mariners used for generations.” The Mercator projection came to enjoy enormous popularity and fame due to the numerous advantages it offered. In particular, it was widely popular in nautical and seafaring circles because it allowed loxodromes or rhumb lines—lines of constant compass bearing—to be represented as straight lines. While shape and direction are preserved throughout the map, size is increasingly distorted with distance from the equator, greatly exaggerating the areas of regions at high latitudes (most famously, Greenland) and

leaving it unable to represent the poles (Figure 1). Its application, however, was muted by the inability to measure longitude accurately during the 16th century.

Undoubtedly, the Mercator projection revolutionized cartography and greatly facilitated its role in European expansionism. It also had deep ideological effects: In standardizing it with rigorous mathematical rules, Mercator helped overcome the long-lasting influence of Ptolemy. Over time, the Mercator projection became the most widely used map projection in history, familiar to every student who has looked at a world map, leading to widespread misconceptions about the relative areal sizes of landmasses in the economically developed Northern Hemisphere, thus sustaining and amplifying discourses of Orientalism and their attendant geographical imaginations. In the 20th century, it was supplanted, or even

displaced, by equal-area projections, such as the Peters projection.

METADATA

Metadata are data about data. More specifically within geography, they consist of digital background information about the origins of geospatial data. The data metadata describe are not necessarily limited to purely electronic data sets but can involve various formats and media. As standard operating procedure within geographic information systems (GIS), metadata play an essential role in identifying data usability and accessibility. A lack of metadata renders a data set less useful or even useless in analysis, since its legitimacy cannot be ensured. The following describes the content, format, standards, uses, and importance of metadata in geography.

Metadata accompany geospatial data in a separate file that includes pertinent information about the data set. The content is designed to allow for situational evaluation of data usability. This record consists of basic identification, quality, spatial reference, organization, attribute, acquisition, and proper usage information on a data set. Common examples of this content are title, author, contact information, equipment

used, processing history, update plan, purpose, rights of use, and geographic projection. Metadata also include the author and currency of the metadata themselves.

The content of metadata follows international (International Organization for Standardization, ISO) or national (Federal Geographic Data Committee, FGDC) standards. These standards specify the different types of information that should be present but do not dictate organizational or transfer protocol. The format for metadata is Extensible Markup Language (XML) or Standardized Generalized Markup Language (SGML), although it can also be a word-processing document, in Hypertext Markup Language (HTML), in Portable Document Format (PDF), or a text file, so long as it accompanies the data.

Organizations use metadata to maintain internal data management standards, to plan spatial data updates and acquisitions, to keep a data inventory for data clearinghouses, and to facilitate spatial data transfer and proper interpretation. They implement metadata to set priorities and maintain data quality and consistency. Metadata can also optimize communication between organizations through a common platform for discussing and documenting data.

Within geography, the importance of metadata rises above that of simple organization, since spatial data sets are incorporated into analysis and decision making. Considering the exponential growth of GIS data availability, there needs to be a mechanism for sorting and evaluating such data prior to acquisition and usage. Metadata maintenance is essential for spatial data management and documentation. This documentation facilitates data location, acquisition, interpretation, and implementation. It provides a clear indicator of the accuracy and currency of data and the legality of data usage. It also identifies the original purpose and scale of the data so that proper incorporation of metadata into mapmaking and decision making can minimize inaccuracy and bias. Metadata play a vital role in geography by providing a common language for geospatial data set interoperation, thus ensuring timeliness and accuracy.

 METROPOLITAN AREA

Metropolitan areas are large population centers (central cities) together with their adjacent zones of influence, where influence may be measured by levels of commuting to the central city or by commercial ties and media penetration—thus typically encompassing rural areas and physically separate satellite towns that are economically integrated with the core city.

Metropolitan areas were an innovation of the U.S. Census, first called “metropolitan districts” in 1930 and only fully developed as “metropolitan areas” for the 1950 Census. Areas were recognized around independent central cities of 50,000 or more people and, for most of the country, consisted of the county containing the central city plus adjacent counties with “significant” ties to the central county, in particular commuting levels of 15% or more to the central city and thresholds of density and nonagricultural employment. In New England, metropolitan areas were defined on the basis of towns, local government units smaller than the county. As these were not statistically compatible with county-based areas for the rest of the country, New England County Equivalent Metropolitan Areas were also defined. However, just as serious a problem of inconsistency and noncomparability resulted from the inconvenient fact that county size and shape varied tremendously across states.

Nevertheless, the metropolitan area designation proved immensely popular, in part because it gave competing cities some sense of their relative

Category	Population	% Share
Metropolitan	226	80
Central city	85	30
Other urban	115	41
Rural	26	9
Nonmetropolitan	55	20
Urban	23	8
Rural	32	12

Table 1 U.S. metropolitan population, 2000 (in millions). By 2008, the metropolitan population is at least 84 % of the total population of more than 300 million. Note that metropolitan areas do contain a sizable rural population and that the “other urban” category, mainly suburbs, exceeds the central city population.

Source: U.S. Census Bureau. (n.d.). *Number of inhabitants, 1950, 1960, 1970, 1980, 1990, and 2000, urbanized areas*. Washington, DC: Government Printing Office.

importance in the national economy, as well as becoming a useful measure of growth from census to census. More important, metropolitan areas soon became the legal units for implementation of myriad federal programs and for the allocation of federal funds. Indeed, the definition of areas is so politically important and sensitive that they are defined by the Office of Management and Budget in the White House and are the subject of battles for autonomy versus inclusion as part of larger areas.

Definitions and rules for delimitation have changed over the years. For example, by 1970, eligibility was based on actual urban agglomerations over 50,000 (urbanized areas), and “consolidated” metropolitan statistical areas were recognized, consisting of adjoining “primary” metropolitan areas with high levels of commuting and economic integration. As of 1990, only commuting to the core urbanized areas was used as a basis for adding outlying counties, resulting in a substantial increase in metropolitan territory and population. Periodically, taskforces have been formed to consider more basic reforms toward greater consistency and comparability, for example, defining areas based on smaller units such as zip codes or census tracts, but the availability of quality data for intercensal years only by counties

has thus far stalled such efforts. However, census tracts and zip-code-based areas (RUCAS, or rural-urban commuting areas) have been defined by the U.S. Department of Agriculture for rural-based programming.

Metropolitan areas should be distinguished from related settlement terms, such as (a) an agglomeration or conurbation, which usually connotes the actual densely built up urban settlement and which in the United States is called an (b) “urbanized area” (the core of any metropolitan area) with more than 50,000 in population; (c) the “business economic area” (BEA), which in the United States is the set of territorially exhaustive economic regions, the cores of which are usually metropolitan areas; (d) micropolitan statistical areas, first defined for the 2000 census and analogous to metropolitan areas but defining areas related to census-defined agglomerations of between 10,000 and 50,000 people; and (e) megalopolis, or larger complexes of closely related metropolitan areas, such as the original megalopolis extending from Boston to Washington (now even farther) and comparable megacities across the globe.

Metropolitan areas have been similarly defined for many countries, but of course with widely varying criteria, rendering comparability very problematic. Perhaps the more directly comparable metropolitan areas are those of Canada, Mexico, Taiwan, and much of the European Union. Most countries do try to define urban agglomerations (but definitions of *urban* vary) and economic regions (comparable with the U.S. BEA regions). And some countries define commuter sheds around major cities for transportation planning purposes.

 MICROWAVE/RADAR DATA

Remote sensing for Earth surface information increasingly uses varied components of the electromagnetic spectrum, such as microwave energy in wavelengths between 1 mm (millimeter) and 1 m (meter). Microwave can be passive or active. Passive sensors record the energy received. There is limited passive microwave sensing primarily at coarse spatial resolution for atmospheric studies. Active microwave sends and receives energy and is much more widely used.

Active microwave is RADAR, an acronym for Radio Detection and Ranging. RADAR systems emit energy, and the returning waves are recorded in intensity and time of travel. The time of travel can be converted to distance from the sensor to the surface and used to determine with considerable accuracy surface distance and elevations by sensors known as Interferometric RADAR (IFSAR or ISAR). RADAR has extensive use in navigation and meteorology, but the focus here is on imaging radar for feature analysis. RADAR advantages over optical sensors include the ability to collect

imagery at night, to penetrate clouds, and, under some conditions, to penetrate into vegetation and hyperarid soils.

Operational Characteristics

RADAR images to the side of the platform at a variable angle are called Side Looking Airborne Radar (SLAR or SAR). RADAR uses different specific wavelengths, such as X, L, C, P, or K band. RADAR energy can also be sent and received in different polarizations, vertical (V) or horizontal (H), for four possible images from one wavelength; HH, HV, VH, and VV (quad polarization). A historic RADAR limitation was that the quality of the data was limited by the size of the antenna. This problem was ingeniously resolved by incorporation of the Doppler effect in processing, caused by slight frequency shifts (caused by the movement of the sensor) between sending and receiving energy known as Synthetic Aperture Radar (SAR).

Variations in RADAR return result in high or low image values, bright to dark tones called backscatter. The backscatter will vary based on wavelength and polarization but is generally determined by surface aspect or geometry, dielectric constant, and texture or roughness.

Applications

There are multiple applications of RADAR. Foremost among these are information in cloudy areas, humid tropics and high latitudes, and areas of limited sunlight and high latitudes in winter. SLAR provides a shaded-relief appearance excellent for delineation of geologic and geomorphic features (Figure 1).

RADAR successfully maps snow and ice in lake or ocean flows and monitors shipping lanes for icebergs. Because oil dampens waves, RADAR can locate oil spills and natural seeps. Other applications include urban analysis, deforestation, biomass estimations in a variety of vegetation communities, flood mapping, agriculture, and generalized land cover mapping (Figures 2 and 3).

RADAR has been acquired from aircraft for more than 50 years. It has been collected from

space since 1978, but systematic space-borne acquisition has only occurred since about 1995. Recently, space-borne RADAR has been obtained by the Canadian, Russian, and European space

MIGRATION

Human migration involves the movement of a person (a migrant) between two places for a certain period of time. It is often considered a permanent relocation, as compared with temporary spatial mobility, which includes all kinds of movement by people, such as commuting, circulating, visiting, shopping, and temporarily working away from home.

This entry first details the most significant forms of migration according to their differing patterns and geographical scale. Next, migration decision making and the ever-changing dynamic processes of migrant behavior are examined. Last, the entry reviews some major constructs that migration scholars have presented as theoretical explanations of this constantly changing livelihood strategy of human mobility.

Forms of Migration

Internal migration within national political boundaries has always been the largest kind of population redistribution enumerated since demographic statistics have been collected and compared at global scales. Its character is often differentiated by the source and destination regions of such internal flows. Hence, rural-to-rural migration, rural-to-urban migration, urban-to-rural migration, and urban-to-urban migration can each feature in an internal migration system of population transfers and exchanges between these geographic places.

Figure 1 Net regional U.S. migration, 2007

Source: Based on Cohn, D., & Morin, R. (2008, December 17). *American mobility: Who moves? Who stays put? Where's home?* (p. 11). Washington, DC: Pew Research Center.

Shorter-distance changes of residence that do not cross the definable boundary of a place (e.g., a city) are more generally referred to as residential mobility, and within urban realms, it is common to distinguish between interurban migration and intra-urban residential mobility. Further differentiations within this group of internal migration streams and counterstreams might be characterized by the growth of megacities, or global cities, in which rapid urbanization occurs within national urban hierarchies. The accelerated growth of these large conurbations in countries of the global South occurs as a consequence of in-migration from rural and urban sources and the accompanying fertility increases of the immigrant populations. Indeed, the 20th century witnessed the rapid urbanization of the world's population, which in 2009 stands at more than 6.7 billion.

Migrants who cross national borders are said to undertake international migration. Immigration is a relatively permanent move into a different country from the migrant's home, whereas

emigration is the relatively permanent move out of the home country. In contemporary times, such international "cross-border" movements can take on a more complex character, with migrants living "betwixt and between" two "life-worlds," experiencing and practicing transnational migration, undertaking repetitive mobilities, maintaining close social contacts, and building multilocal, transnational networks of kith and kin.

With increasing globalization, rates of international migration have grown in recent years. In 2006, there were 191 million international migrants in the world, with this estimate representing more than a twofold increase from 76 million in 1960. Whereas many countries are now "sending sources" of international migration, relatively few countries are the targeted hosts of immigration streams, and since immigration policies invariably restrict and control entrance to these receiving countries, migrants have long sought irregular means of entry and access to work "across borders." Most, however, pursue legal means of entry, including short- and

Figure 2 Average annual rate of domestic net migration by county: 2000–2004

Source: Perry, M. J. (2006, April). *Domestic net migration in the United States: 2000 to 2004* (Current Population Reports) (p. 11, figure 4). Washington, DC: U.S. Department of Commerce, U.S. Census Bureau. www.census.gov/prod/2006pubs/p25-1135.pdf.

long-term sojourning, the acquisition of visas for study, educational advancement and work permission, and often lengthy legal immigration and permanent residence petitioning and asylum petitioning. Irregular migration is the currently acceptable label for those undertaking nonlegal means of entry, replacing the plethora of xenophobic labels that have commonly been used in many a contentious anti-immigration debate, such as “illegals,” “illegal aliens,” “undocumented,” “unauthorized,” “overstayers,” “clandestine entrants,” “failed asylum seekers,” and “unwanted foreigners.”

Decision Making: Voluntary Versus Involuntary Migration

Migration can also be differentiated according to the conditions that prompted the decision to move away from the migrant's original place of residence, with a dichotomous categorization distinguishing a move as either voluntary or involuntary, “forced” migration. Voluntary migration is often economically driven, is selective by age and resource endowment, and includes the whole range from unskilled workers to highly skilled workers seeking better opportunities, experiences, and incomes in more distant labor markets than the ones they can access by staying in their original homes (including commuting and temporary work off-farm or in nearby urban centers). Voluntary migration is also a decision made and undertaken collectively by migrants and partners, migrant families, and selected members. On the other hand, the migrant's dependants—infants, young children, female partners—who are “tied movers” can be considered to be migrating involuntarily if not involved in the decision making by the household head or patriarch. In short, the social (and gendered) contexts of family power relationships often intervene in decision making concerned with the migration of families and family members.

Theoretical Explanations

Certain historical and more contemporary explanations of voluntary and involuntary migration amply demonstrate the richness of explanations of human migration as both historical and spatial

contexts vary and change, thereby rendering this mobility option extremely flexible, ever changeable and changing. There is now a growing consensus that multiple theoretical explanations reign, not one all-encompassing single theory, though the pathway to this holistic generalization has been built on many informative constructs, with some of the most exemplary detailed below.

In the late 18th century, Ernest George Ravenstein used mixed methods of analysis to inductively generate a series of “laws of migration” that attempted to explain and predict migration patterns both within (internal migration) and between (international migration) nations. Two concepts, absorption and dispersion, were derived to explain county increases and decreases, respectively, as Britain went through its urban-industrial transformation during the second half of the 19th century. Ravenstein's first paper in 1885 proposed seven “laws of migration” or generalizable regularities in internal patterns of movement: (1) most migrants only proceed a short distance and toward centers of absorption; (2) as migrants move toward absorption centers, they leave “gaps” that are filled up by migrants from more remote districts, creating migration flows that reach to “the most remote corner of the kingdom”; (3) the process of dispersion is inverse to that of absorption; (4) each main current of migration produces a compensating countercurrent; (5) migrants proceeding long distances generally go by preference to one of the great centers of commerce or industry; (6) the natives of towns are less migratory than those of the rural parts of the country; and (7) females are more migratory than males. Several of these original seven laws included assertions that were later considered “additional laws of migration”; (8) most migrants are adults; (9) large towns grow more by migration than by natural increase; (10) migration increases in volume as industry and commerce develop and transportation improves; (11) the largest volume of internal migration is rural-urban migration; and (12) the major determinants of migration are economic forces.

This view should remind us that internal migration became an adaptive strategy for rural people in the past centuries, as their agrarian livelihoods were transformed. Ravenstein's “laws,” however, did not explain why some rural adults would

A migrant family waiting in a bus station in Cuiaba, Brazil, in September 1985. During the 1970s and 1980s, many families such as these immigrated to territories of the Amazon such as Rondonia and Acre in search of a better life.

move while others would not. For this, Guy Standing's conceptual explanation is insightful.

Standing proposed that four conditions needed to exist to make peasants in traditional communities become migrants, the conditions being reflected in the decay in the traditional mode of exploitation (i.e., feudalism): (1) migration must exist as an acceptable response to adversity or frustrated aspirations; (2) peasants come to identify their condition as neither just nor inevitable, because some reciprocal relationship between them and their feudal landlords has been violated; (3) staying and instigating a revolt is seen as having a minimal chance of success, because the peasants are not organized in their objection to oppression, violence, or economic threats and they lack communal strength and unity; and (4) peasants come to reject customary forms of

exploitation because of a growing sense of deprivation and despair that things won't get better and because of increases in their disadvantageous position in contrast to their previous situation.

Changing the scale from internal to international mobility, Douglas Massey, in a commentary on Mexican international migration and development relations, developed an interesting theoretical construct to explain the prevalence of emigration in developing countries. Three structural conditions were said to characterize the development process: (1) the cyclical nature of industrial expansion in urban areas, paired with the more or less constant pressure for out-migration from rural areas, determined by capital formation, enclosure, and market creation, which together destroy the basis of peasant social organization and weaken their ties to rural

communities; (2) discontinuities in economic growth across time and space (i.e., uneven geographic distributions within countries and between countries), producing cyclical constrictions of opportunity in developing urban economies paired with expansions of opportunities in growing (metropolitan/core) economies abroad; and (3) declining real costs of transportation and communication, actualized by increasing access to reliable and affordable systems.

Discussing the dynamic deepening of the Mexico-U.S. migration system, Massey also explained why there is a tendency for international emigration to become progressively independent of the economic conditions that originally caused it, referring to this maturing of the migration system as the result of cumulative causation. Three mutually reinforcing processes appear to be at work in this transformational dynamic: (1) transnational network formation; (2) agrarian transformation, via emigrant earnings, remittances, and returnee “demonstration effects”; and (3) the evolution over time of deprivation and impoverishment in source communities.

Now, finally, returning to forced migration, this label has become a suitable categorization of a range of global movements in which an element of coercion exists, including threats to life and livelihood arising from biophysical or social/anthropogenic crises—environmental disasters, chemical or nuclear disasters, famine, civil war, genocide, or development-induced displacement. Natural disasters, environmental degradation and destruction, warfare, civil strife, banditry, warlord enmity, genocide, and every imaginable horror brought about by military power struggles and the accompanying “collateral damage,” which threatens and kills local civilian populations, are contemporary forces instigating and perpetuating such involuntary, forced migrations. Refugees, asylum seekers, internally displaced persons (IDPs), and development-induced and environmental-disaster-displaced persons are some of the main groups forced to flee their homelands and seek asylum beyond their nation’s borders. A majority of these displaced persons and refugees are the rural poor and powerless in the global South—Africa, Asia, and Latin America—who have consistently suffered from disruption, destruction, and displacement in recent decades.

A growing practice among international criminal groups, syndicates, and organizations is to profit from such forced migration by ushering in a new form of slavery and coercion in which the migrants are treated as disposable commodities. These underground organizations prey on young women and children by offering hope, while tricking, brutalizing, and selling them into prostitution and sex working, sweatshop labor, and similar illicit, dehumanizing and/or dangerous occupations in which they have little autonomy or basic rights and human dignities. The International Labour Office has recently estimated that at least 12 million people work as slaves or in other forms of forced labor and as many as 2.5 million are in forced labor as the result of cross-border trafficking, with approximately half being employed against their wills in sex trafficking.

MILITARY GEOGRAPHY

Military geography generally applies the concepts and techniques of geography to the study of military problems, situations, and activities. It examines, among other things, the causal effects of physical geography (e.g., terrain, climate) on military battles, campaigns, and wars. More recent developments in the discipline, however, have broadened the scope of military geography to include the study of military operations other than war (known by the acronym MOOTW), as well as the impacts of militarism on societies and the environment and also the use of environmental resources as components of military-related activities.

Military geography is intimately associated with the development of the discipline, an association that dates far back to early Greece. Thucydides's account of the Peloponnesian War (431–404 BCE), for example, is an early application of geographic perspectives to the study of military activities. From a non-Western perspective, Sun Tzu's *The Art of War* may also be considered an early example of military geography. The birth of "modern" military geography, though, is generally marked by Théophile Lavellée's *Géographie Physique, Historique et Militaire* (1836) and Albrecht von Roon's *Militärische Landerbeschreibung von Europa* (1837). These two publications firmly established the connection between military campaigns, imperialism, and the formation of the nation-state in Europe. In the United States, W. C. Brown is credited with publishing the first text on military geography, although it was the writings of Alfred Thayer Mahan that provided the main American contributions to the emergent field of military geography. A naval historian, Mahan wrote more

than 20 books; the most important of his works were his 1890 *The Influence of Sea Power Upon History, 1660–1783* and its 1892 companion, *The Influence of Sea Power Upon History: The French Revolution and Empire, 1793–1812*. Mahan's writings, coupled with those of the British geographer Halford Mackinder, were also influential in the development of both political geography and geopolitics.

Throughout the 20th century, military geography has been significantly influenced not only by changing technologies (e.g., air photos, remote sensing, geographic information systems) but also by military conflicts. Indeed, it is often impossible to disentangle these two external influences on the development of military geography. During World War I, for example, geographers provided written descriptions of the physical landscapes involved in military campaigns. Other geographers participated in the 1919 Paris Peace Conference, which led to the Treaty of Versailles, and in the subsequent attempts to redraw the political boundaries of postwar Europe. Academically, military geographers produced numerous writings, emphasizing the applied and practical aspects of geography for the study of military-related problems. The works of D. W. Johnson—*Topography and Strategy in the War* (1917) and *Battlefields of the World War, Western and Southern Fronts: A Study in Military Geography* (1921)—epitomize much of the work of military geographers during this period.

After World War II, the wartime experiences of many geographers led to significant changes within and beyond academia. During the war, for example, many governmental agencies sought persons with the diversity of training and education that the study of geography provided. Hundreds of geographers were engaged in the war effort, being employed in the Office of Strategic Services (OSS), the War Department, the Intelligence Division, and the Army Map Service. Women also contributed to the application of geographic perspectives and techniques to military problems, notably in the fields of mapping and surveying. Within academia, geographers applied their research activities to studies that would have a direct bearing on military-related problems. R. A. Bagnold's *Physics of Blown Sand and Desert Dunes* (1941), for example,

was very important for military planning related to the North African campaign—namely, how mechanized vehicles would operate in Aeolian environments.

World War II, and the contributions of military geographers, also provided a catalyst to more far-reaching changes in the structure of academic geography. For example, the efforts of F. Webster McBryde (who was employed in the War Department) led to the formation of the American Society for Professional Geographers (an association that later merged with the long-standing and more research-oriented Association of American Geographers). Equally important were the writings of individuals such as Edward Ackerman and Fred Schaefer, who argued that regional geographers, as a whole, were not well trained as social scientists and that geography, as an applied discipline, required a greater emphasis on, and training in, systematic specialties. Consequently, the military experiences of World War II, and of the geographers who participated in many facets of that conflict, facilitated the growth of a more systematic—and nomothetic—approach to geography and a move away from regional geography. Subsequent and continued advances in quantitative methods and air photo interpretation remained techniques of the subfield.

Just as World War II heralded a blossoming of military geography, the tumultuous events of the 1960s—especially America's involvement in the Vietnam War—led to a decline in military geography as a subfield. Traditional work did continue, but geography as a whole moved away. As Eugene Palka (2003) writes, "Contributing to the war effort in Vietnam came to be regarded as irresponsible by many members of the AAG," and consequently, the "controversy surrounding the Vietnam War cast a persistent shadow on military geography throughout the 1970s" (p. 506).

The end of the Cold War, and the hegemonic rise of the United States as the sole global superpower, contributed to a renewed—and reworked—military geography. "Classical" studies of military geography continued, as exemplified by the writings of Palka, Arnon Soffer, Julian Minghi, and Harold Winters. However, the late 20th and early 21st centuries also have witnessed an enlargement of the

scope of military geography, to include, more explicitly, studies of peace and peacetime operations, nuclear disarmament, and the diffusion of arms and arms manufacture. Especially noteworthy are two edited volumes: David Pepper and Alan Jenkins's *The Geography of Peace and War* (1985) and Colin Flint's *The Geography of War and Peace: From Death Camps to Diplomats* (2005).

The changing terrain of military geography was given impetus by a series of seminal publications in the early 21st century. Among these was Rachel Woodward's 2005 article, "From Military Geography to Militarism's Geographies: Disciplinary Engagements with the Geographies of Militarism and Military Activities" in *Progress in Human Geography*. Woodward makes a distinction between military geography and "militarism's geographies," where the latter refers to

the shaping of civilian space and social relations by military objectives, rationales and structures, either as part of the deliberate extension of military influence into civilian spheres of life and the prioritizing of military institutions, or as a byproduct of those processes. (p. 721)

A revitalized military geography has led many scholars to cast a critical eye inward. The works of Trevor Barnes, Matthew Farish, and Trevor Paglen, for example, critically examined the nexus of geography and the military-industrial complex and highlighted the symbiosis that exists between war, imperialism, and geography. Geographers have also transformed traditional areas of inquiry within the subfield. Military geographers, for example, have long worked at the intersections of human and physical geography. Traditionally, this work emphasized the impact of physical processes, such as terrain and climate, on the conduct of military campaigns and battles. More recent work, though, has examined the political economy of environmental resources (e.g., oil and diamonds) and how these resources contribute to military conflicts.

Institute's annual *SIPRI Yearbook 2007*, the aggregate military expenditure by all national governments in 2006 was \$1.024 billion in market exchange rate (MER) terms. Adjusted for inflation, this figure marked a 37% growth in military budgets since 1997. This level of increased military spending follows a long trend that dates to World War II and that greatly accelerated during the Cold War. The levels of military spending over the past 60 years have been—and continue to be—a dynamic force that has deeply altered the fabric of social, political, spatial, and economic relationships, from the scale of the local to that of the global.

There are four fundamental aspects of military expenditures. First, high levels of military expenditure are a prerequisite for the geopolitical power of a nation-state, a point exemplified by a global U.S. hegemony, which is founded upon enormous levels of military spending. Second, preparation for war has increasingly integrated private firms, modern production practices, and technological innovation with government spending. This mixture has created a military-industrial complex dedicated to the production of arms. Third, military spending has spatially reorganized local, national, and global economies in a manner quite different from that of the civilian economy. Fourth, high levels of military spending accelerate the international proliferation of advanced weaponry. Finally, there are significant methodological problems inherent in all military expenditures data that must be addressed in geographical research, especially given the polemical debate that often infuses popular discourses on national spending.

Military Spending and the Production of Geopolitical Power

Ranking national military expenditures in MER terms, when combined with similar data from previous years, reveals the close link between military spending and the production of global geopolitical power. The major military spender in 2008 was the United States, with \$6.071 billion. This accounts for 41% of world military spending in the same year. China, with \$84.9 billion, came in second. France and the United Kingdom each spent roughly \$65 billion, putting them in

MILITARY SPENDING

Military expenditures, broadly defined, are the aggregate funds spent by a national government for military-related purposes. According to the Stockholm International Peace Research

third and fourth place, respectively. Russia ranked fifth, with \$58.6 billion. Russia's status marks a stark contrast to the position of the former USSR, which typically vied with the United States for the title of the world's biggest military spender during the Cold War.

Although Tables 1 and 2 give estimates of military spending in constant U.S. dollars, estimates of relative expenditure levels can also be given in terms of purchasing parity power (PPP), which reflects national differences in the costs of weapons systems. Expressing military expenditures in PPP terms is necessary because there are vast differences among states in the quantities of capital and labor that a given amount of funds can purchase. For example, \$100 billion

Rank	Country	Spending (\$ b.)	World Share (%)

spent in China will purchase significantly more armaments or military services than the equivalent amount spent in the United States. Equalizing national differences in costs tends to reduce the relative size of military expenditures in Western Europe and Japan and raise the rankings of poorer countries such as China, India, Russia, and Saudi Arabia. Notwithstanding this caveat, it should be immediately apparent that the current U.S. hegemony in world affairs is due, in large part, to its unparalleled dedication funding its military.

These enormous expenditures, particularly those of the United States, are the root of all modern geopolitical power. They have also created a historically novel military-industrial complex dedicated to the manufacture of the weapons of war, which has extended the social effects of military spending well beyond the battlefield and into the fabric of civil society.

The Military-Industrial Complex

Aggregate military expenditure figures break down into numerous subcategories, including

labor and health care costs for personnel; operations and management costs for logistical management; procurement costs for new weapons, hardware, ammunition, and other supplies; research, design, testing, and engineering (RDT&E) costs of designing new weapon systems; and construction and maintenance costs for bases, supply depots, and housing for personnel. Labor, operations and management, health care, and construction costs are a significant portion of most military spending, particularly within the United States, where military service members receive free housing and health care. This entry concentrates on the effects of procurement and RDT&E expenditures, since it is these two categories that have had the most profound impacts. This phenomenon lies in the heart of what President Dwight Eisenhower called the “military-industrial complex,” and it is radically dissimilar to any other segment of the global economy in form and function.

World War II introduced substantial changes in the material preconditions for battlefield superiority. Militant nationalism and the implementation of Fordist production practices produced a new model of warfare in which military victory was suddenly predicated on industrial capacity. Large-scale industrial production of armaments became a prerequisite to national survival, and mechanized weapons of war began rolling off assembly lines in large volumes. Producing these weapons in prodigious numbers necessitated co-opting civilian resources, production lines, and technological knowledge at a scale achievable only by a national government directly managing the civilian economy. This style of industrial management birthed a novel relationship between the private and the public sectors of the economy: the military-industrial sector, comprised of nominally civilian businesses dedicated to production of complex, mechanized armaments, funded through military procurement budgets.

The detonation of the atomic bombs over Hiroshima and Nagasaki in 1945, and the ensuing Cold War tensions between the United States and USSR, marked another watershed moment in the practices that underlie modern preparations for warfare. Globally, military budgets declined only briefly after World War II, and rose with the Korean War. The massive influx of capital into

scientific research ushered in a new era of innovation led by military innovation that emphasized not the capacity to manufacture arms per se, but rather the extension of weapons capabilities on the battlefield through technological innovation. Moreover, the new commitment to innovation enshrined in rapidly increasing military RDT&E expenditures focused on the creation of “smart weapons” through the use of electronics and computers. The result was a blizzard of technological advancements in weapons capabilities, many of which found their way into the civilian sector, including, for example, microcomputers, an outgrowth of mechanical calculators designed to compute artillery ballistic tables; the Internet, initially a project of the U.S. Defense Advanced Research Projects Agency; satellite surveillance and communications technologies, including global positioning systems and remote sensing technologies; and the vast majority of early aviation advancement, including the jet engine, to name a few. The age of the ICBM and cruise missile had begun.

Tracing the historical trajectory of the global military-industrial economy makes clear the link between procurement and RDT&E spending and the creation of a distinct sector of the economy. Measured in terms of the total value of all domestic and international arms sales, in 2006 U.S. companies represented 40 of the largest 100 armament manufacturers, another 32 firms were based in Western Europe, and yet another 6 were Japanese. These combined to form 78 of the 100 largest arms companies in the world, all found within countries typically viewed as bastions of democratic freedom; an additional nine firms were Russian and three were from India.

The historical and empirical links between military spending and arms manufacturing foreground the single most salient feature of military expenditures: an institutionalized relationship between government and industry that, while mediated by money, is fundamentally political in nature. Much of the economic literature is steeped in neoclassical economic discourse, which has a tendency to misapply market-based economic theory to a structurally unique segment of the economy. This error obfuscates the fundamental differences between the military-industrial sector and the civilian economy, particularly a “market”

characterized by a monopsony (the Defense Department) and oligopolistic arms producers.

This critique is further extended by recognizing the argument that the pricing mechanism commonly utilized by national governments in procurement and RDT&E is significantly different from the operations of the market economy, particularly those inherent to economies of scale. Needless to say, governments are reluctant to purchase multimillion-dollar weapon systems when a significant percentage might be defective; not only is it a wasted expenditure, it also has the potential to be disastrous if a weapon fails at a critical point in battle. Thus, the practice of “cost-plus” contracting arose as a common method to minimize defect rates. Under the cost-plus system, national governments agree to pay all of the costs of design and production, including overruns, in addition to a profit which is determined as a percentage of those costs. The emphasis is not placed on obtaining a weapon at the lowest price, but on buying weapons that work irrespective of cost. The ultimate effect, however, is to expressly subvert the normal operations of supply and demand common in civilian markets.

Typically, military expenditures are expressed as a proportion of gross domestic product (GDP). This approach, however, underestimates military spending. Unlike the bulk of government spending, these expenditures are not transfer payments, nor are they investments in infrastructure that is indirectly productive (e.g., roads and bridges). Yet such expenditures do not belong in any of the “private” categories either, differing in two major ways: the civilian macroeconomy is comprised of many actors making numerous and diverse small investments, whereas military expenditures represent a vast flow of capital directed at significant fewer projects. Moreover, RDT&E spending is immune to the normal constraints common to normal economic markets, which ensures that contractors can maintain unpromising avenues of research well past the point at which they would have been terminated in the civilian market.

The cost of each new generation of weapons is dramatically accelerating over time. Accelerating costs, driven by the increasing emphasis on high-technology aerospace innovations and cost-plus contracting, are a key factor driving the continued expansion of military spending. Expanding

the capability of each successive generation of weaponry is becoming increasingly difficult, and, hence, increasingly expensive.

Concurrent with, and partially as a response to, the escalating unit cost of weapon systems is an increasingly oligopolistic industry structure, coupled with a process of subcontracting the production of dual-use technologies, that is, products with military applications that are manufactured for the civilian market. The roll call of defense mergers from 1990 to 2001 is telling: The total number of U.S. firms capable of producing advanced fighter/bomber aircraft declined from nine to two; the total number of missile manufacturers fell from 14 to 4, with only one company capable of producing air-to-air missiles; firms with the capability of producing space-launch vehicles fell from six to two; and the manufacturers of major avionic subsystems were, in many cases, bought by the dominant aerospace contractors. Consequentially, U.S. defense contracting increasingly resembles a monopoly-monopsony relationship—the very antithesis of the competitive market. This process of consolidation is paradoxically coupled with an expansion in subcontracting, since advanced weapons require an increasing number of intermediate inputs (which themselves require high-tech inputs in turn). The new defense megafirms outsource production in an effort to reduce costs and maximize profit. Unfortunately, good data on subcontracting practices do not exist, but the available data suggest that defense firms, due to the specialized nature of their products, tend to subcontract with each other rather than with other industries. The arms industry in Western Europe, too, has undergone consolidation and intensive subcontracting, with, for example, pan-European defense contractors Alenia Aeronautica, BAE Systems, and EADS forming a consortium to manufacture Europe’s next-generation fighter aircraft, the Eurofighter Typhoon.

Despite the massive structural changes in the industry and increasing unit costs, profits in the defense industry remain high and continue to grow. These expenditures ultimately determine the size and shape of the defense industry, since there is no civilian demand for missiles or tanks. Moreover, it is unclear whether current levels of investment in RDT&E and armament production

can continue unabated, and the implications of this trend for the current military powers are indeterminate at best; the U.S. government, in particular, has begun to struggle under a mountain of debt incurred in funding its advanced weapons programs.

Geographic Patterns of Military Expenditures

Because of their role in the military-industrial sector, military expenditures have produced numerous ancillary effects at a wide variety of spatial scales. At the subnational scale, such spending produces substantial variation in local and regional economic structure and growth. At the global scale, military expenditures have produced a burgeoning international arms trade. Each of these components has its own, distinctive geography.

Impacts in the United States

In *The Rise of the Gunbelt: The Military Remapping of Industrial America*, Ann Markusen documents the creation of a distinctive subregion within the United States, the titular “Gunbelt” of America. In Markusen’s view, the Gunbelt—centered on the “holster” of Texas and stretching down the west coast, through the South, and up the eastern seaboard—accounts for most of the regional economic variations within the United States. In particular, military RDT&E and procurement expenditures, which heavily favor the Gunbelt states, have actively contributed to the decline of traditional manufacturing regions of the north and actively created a new locus of U.S. industrial capacity, particularly in the West. This process has both shifted industrial capacity and motivated U.S. citizens to relocate internally as they follow the numerous employment opportunities created by the defense industry. High levels of defense expenditures also inject money into localities, which can have a positive effect on local economic prosperity. Contrariwise, the decision to cancel the flow of military funds into a region can be disastrous for cities and towns dependent upon them; the loss of contracts for aerospace contracts would, for example, have serious implications for the prosperity of Seattle, many of

whose inhabitants are dependent upon the prosperity of aerospace giant Boeing. Because it is largely divorced from the wider operations of the civilian economy, military spending has the potential to create local prosperity in the midst of a wider economic recession, or local decline during a period of national prosperity—geographic variations that would otherwise be inexplicable.

Markusen notes that there are two general patterns to defense spending in the United States. During the Cold War, military spending tends to focus on the Gunbelt itself, with funds going to high-tech aerospace manufacturers and RDT&E research facilities primarily located on the west coast and in Texas. During times of “hot” war, many more contracts go to traditional manufacturing regions states, where stocks of ammunition and other low-tech ordinance are replenished via low-tech mass production.

Transnational Impacts

Military expenditures also produce transnational variations, in the form of a distinctive pattern in arms trade. National governments, seeking to prevent local job losses and keep their military-industrial base “warm” during times of peace, increasingly use exports as a means to encourage private arms production. Direct transfers among countries are the sale or gift of a complete weapon or weapon system, whereas licensed production involves the underlying sale or transfer of production techniques and associated technologies necessary to actually make a particular weapons system. The United States leads the world in both categories of arms transfers and is the largest distributor of all major weapons systems, and the recipient nations that it favors tend to receive the bulk of the global flow in arms. Small arms, which require much less in the way of technology to manufacture, are a scourge all by themselves; they are, however, easy to make, cheap to buy, and almost impossible to track. Stemming the tide of conventional weaponry flowing from the industrialized world is an almost intractable problem, however, since reductions in national military budgets counterintuitively produce an increasing volume of international transfers, as national militaries sell off stocks of older weapons to make up for budgetary shortfalls.

Figure 1 The Gunbelt in 2008. The majority of U.S. military expenditures are concentrated in the South and West.

Source: Adapted from data in U.S. Department of Defense. (2008). *Projected defense purchases: Detail by industry and state, calendar years 2008 through 2013* [Online]. Retrieved March 8, 2009, from www.ra.pae.osd.mil/ra/DEPPS2008.pdf.

The Veracity of Expenditure Data

Great care is necessary to responsibly utilize military expenditure data, particularly given the culture of secrecy and polemical popular discourse surrounding the subject. Even when a dedicated third party devotes significant efforts to itemizing military spending, definitions of what constitute a military expenditure vary widely by source.

There are numerous ways to decrease military spending on paper, especially when relying on totals self-reported by a national government; differing methods of aggregation will produce substantially different aggregate totals. Within the U.S. federal budget, for example, there are numerous items that are reported as civilian expenditures, but are actually earmarked for dedicated military projects. For example, funding for nuclear weapons research is technically

allotted to the Department of Energy, not the Department of Defense, and the donation of military hardware or supply of military loans to foreign governments is often handled by the Department of State. The federal budget for military spending also excludes civil defense costs, paramilitary organizations such as the National Guard, demobilization and disarmament costs, current expenditures for past military activities, and veterans' benefits and health care are separately funded by the Veterans Administration and classified as civilian expenditures. The exclusion of these items produces a substantial undervaluation for the largest military budget in the world, and ignores one of the fastest growing budgets within the U.S. government (the Department of Homeland Security), as well as all expenditures dedicated to servicing debt accrued during military buildups or wars.

Figure 2 U.S. defense budget as percent of GDP. Although it has declined to roughly 5% of GDP, the official Defense Department budget excludes numerous items such as veterans' benefits, military foreign aid, spy satellites, and research on nuclear weapons.

Source: Author.

This problem expands enormously in complexity as it expands in scale, with each country possessing a different language(s), governmental idiosyncrasies and budgetary conventions. As a rule of thumb, however, aggregate data tend to reflect a substantial undervaluation of military budgets in Western Europe, the United States, and Japan, and overvaluation in the rest of the world.

Conclusion

Despite the continued expansion of global military expenditures, normative political discourse among the nations of the West, most especially within the United States, tends to minimize the financial cost of developing, outfitting and supporting modern militaries.

MILLER, HARVEY J. (1962–)

Harvey J. Miller is well known and respected for his research involving time-geography, transportation, and spatial analysis and modeling. His research in time-geography has built on the work of Torsten Hagerstrand by analyzing space-time accessibility. Miller's research involves exploring both theoretical concepts and methodological approaches to better understand how individuals make decisions in a given environment and the patterns that emerge as a result. He emphasizes the need and the potential for people-based spatial analysis to better represent the dynamics of individual activity patterns in both space and time. One application has been substantive contributions to transportation geography. He has built methods for using space-time accessibility measures to evaluate the flow of traffic to mitigate congestion. His research accomplishments have been recognized with several awards, including the Geoffrey J. D. Hewings Award from the North American Regional Science Council in 1997 and a Superior Research Award from the University of Utah in 2004.

Miller is currently a professor of geography and chair of the Department of Geography at the University of Utah. His education began at Kent State University, where he earned a Bachelor of Arts degree in 1985, followed by a Master's of Arts degree in geography in 1987. In 1991, he earned his PhD in geography from Ohio State University. On completing his doctorate, he became an assistant professor at the University of Utah, where he has continued on as department chair. He has influenced and shaped much of the department's reputation in quantitative analysis and modeling in urban economic geography, population migration, biogeography, and natural hazards.

Miller has served on numerous national and international organizations, reflective of his areas of interest and expertise. Nationally, he serves on the Committee on Geographic Information Science and Applications, Transportation Research Board (2003–2005, board member; 2005–2011, cochair); he has been on the board of the University Consortium for Geographic Information Science (2000–2003) and on a policy committee of the National Research Council to identify data needs for place-based decision making. Internationally, he serves on several editorial boards, including being the North American Editor for the *International Journal of Geographical Information Science* (2000–2004).

MINERALS

The International Mineralogical Association (IMA) defines a mineral species as an element or chemical compound that is normally crystalline

and that has formed as a result of geological processes. There are currently about 4,100 such species known. But minerals are more than just chemical elements and compounds. They are the building blocks of the rocks that form mountain chains and the sands of deserts and beaches. Minerals, and the rocks they constitute, record the history of the Earth and are the source of the metals and raw materials on which our everyday lives so greatly depend. Minerals are the enablers of civilization. They have been used by humans from the Stone Age through today. Minerals are useful for one of two reasons: They either have a useful property (e.g., talc is soft, inert, and white, rendering it useful as a cosmetic) or contain an important element (e.g., chalcopyrite [CuFeS₂] is an important ore of copper). The first group comprises the *industrial minerals*, whereas the second is often referred to as the *ore minerals*.

Characteristics and Classification

The characteristic criteria of minerals are implicit in their geological definition: Minerals are naturally occurring, are solid, have a definite chemical composition and an orderly crystal structure, and are typically inorganic. Quartz (hexagonal SiO₂), halite (or rock salt, cubic NaCl; see first photo),

The outward appearance of these halite crystals is a consequence of their internal cubic structure.

Source: Photograph taken by author of specimen at the A. E. Seaman Mineral Museum.

and gold (cubic Au) are familiar examples. There are, however, a few exceptions to the rule. For example, native mercury is considered a mineral even though it is normally liquid at ordinary temperatures, and opal is a mineral, although it is frequently amorphous and contains a variable amount of water. But for the vast majority of minerals, the IMA definition works well. Thus, diamond is a mineral, but coal is not; ice is a mineral, but water is not.

Together, the chemical composition and crystal structure of a mineral define it as a particular species and determine all of its chemical and physical properties. Mineralogists classify minerals according to their chemistry (e.g., sulfides, oxides, carbonates). Within each chemical division are individual groups of minerals based on similarity of their atomic structures. The classification hierarchy is simple, consisting of only three levels: (1) group, (2) species, and (3) variety. A common example is the calcite group, which includes various species such as calcite, siderite, magnesite, and rhodochrosite, among others (see second photo). These minerals all have similar structures and a general formula M²⁺CO₃, where M²⁺ is a divalent metal cation, such as Ca²⁺, Fe²⁺, Mg²⁺, or Mn²⁺. When Ca²⁺ is the dominant cation, the species is calcite; if Fe²⁺ predominates, the species is siderite; and Mg²⁺ and Mn²⁺ result in magnesite and rhodochrosite, respectively. Sometimes a particular color variant or other distinguishing feature earns a species a varietal name. Thus, colorless calcite is known as “Iceland spar,” whereas red corundum is ruby, and purple quartz is amethyst.

Minerals derive their names from several sources, and those proposed for new species being described today must be approved by the IMA before they are generally accepted by the scientific community. There are few hard-and-fast rules dictating how a mineral should be named. Some are named after people (e.g., millerite [see third photo] for W. H. Miller, a famous British mineralogist), while others are named for geographic places (e.g., calumetite for Calumet, Michigan, where it was first found). Minerals such as cavansite (a calcium vanadium silicate) or nahpoite (NaHPO₄) derive their names from their chemical compositions, while others, such as hematite, are named for their physical

Cleavage rhombs of calcite group species (A) siderite, (B) magnesite, (C) rhodochrosite, and (D) calcite

Source: Photograph taken by author of specimen at the A. E. Seaman Mineral Museum.

appearance. Hematite commonly occurs in earthy red masses (in Greek, *haimatitis* means blood red). Magnetite is highly magnetic, and azurite is azure blue. One species, minrecordite, is even named after a popular journal, the *Mineralogical Record*.

Because of their different atomic structures, variable compositions, and different environments of formation, crystals of various minerals can assume myriad shapes and colors. The outward overall appearance of a crystal is known as its “habit” and is governed by both intrinsic and extrinsic factors. Intrinsically, a mineral’s atomic structure plays a significant role in governing its outward appearance. It determines what symmetry is possible and what is not. We don’t see six-sided halite crystals because the underlying atomic structure of that mineral is based on the fourfold symmetry of a cube. Depending on their size and

charge, various elements may be incorporated into its structure as the crystal grows. Some may act as chromophores, absorbing specific wavelengths of light, thereby imparting different colors to the original mineral. While the atomic structure dictates which elements it might accept, it is the composition of the fluids available to the growing crystal that determines whether or not those elements are present. Sometimes, certain dissolved impurities may prevent the growth of one particular crystal face from developing in favor of another, leading to distorted crystals. Additional extrinsic factors such as the presence or absence of fluxing elements, temperature, pH, and time have an influence on the final outcome of what the mineral looks like. The diversity in physical appearance within even a single common species such as quartz or calcite is staggering (see fourth photo).

Mineral-Forming Environments

For convenience, the means by which minerals form may be grouped into four basic geological processes: (1) precipitation from aqueous solutions, (2) crystallization from magma, (3) chemical alteration, and (4) recrystallization in the solid state by heat and pressure (metamorphism). These processes may act independently or in combination to form various minerals. Species with limited fields of stability tend to occur in few geological environments, whereas those stable over wide ranges of physical and chemical conditions are found in a greater number of geological environments. Thus, heavily hydrated minerals such as mirabilite ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$) are found in salt lakes and playas, but they quickly dehydrate into less hydrated species on exposure to air. Quartz, on the other hand, is stable over a broad range of conditions and is a common constituent of igneous,

These colorless crystals (A) and banded agate (B) are both the same species: quartz.

Source: Photograph taken by author of specimen at the A. E. Seaman Mineral Museum.

sedimentary, and metamorphic rocks alike, as well as being the main component of many sands.

One of the simplest ways certain minerals form is by direct precipitation from aqueous solutions.

If a glass of saltwater is left out on the counter-top, the water slowly evaporates, concentrating the dissolved salt to a point where the solution becomes supersaturated, and salt crystals begin to form on the bottom of the glass. This is not unlike the process that forms salt flats in playa lakes or, on a grander scale, beds of rock salt such as that hosted by the great Salina formation, stretching from New York to Michigan and formed by the evaporation of an ancient sea. Halite, gypsum, potash, and other minerals formed in a similar manner are called evaporites and constitute an economically important group of industrial minerals.

In the case of evaporites, the water is of meteoric origin and relatively cool. In the case of hydrothermal deposits, the water is hot and may be meteoric, magmatic, or tectonic in origin. Yellowstone National Park provides a classic example of a meteoric hydrothermal system. There, groundwater is warmed by proximity to a magma chamber that enables it to dissolve silica, calcite, and other minerals that precipitate on cooling to form cones around erupting geysers or extensive travertine flows at Mammoth Hot Springs. Similarly, brines flowing through deeply buried sediments are warmed as a consequence of burial and may dissolve and concentrate various metals as chloride complexes. If these brines later encounter a source of reduced sulfur, lead and zinc sulfides may precipitate to form galena and sphalerite, creating an economically important Mississippi Valley Type deposit, such as in the famous Tri-State Mining District of Kansas, Oklahoma, and Missouri.

As magmas cool, individual minerals begin to crystallize out. Those with the highest melting temperatures are the first to crystallize (e.g., olivine, pyroxene, anorthite). As the process continues, various elements are selectively removed from the melt, and ions of unusual size or charge that don't fit into the structures of the precipitating minerals may accumulate and form a hydrothermal solution rich in metals such as gold, silver, bismuth, tin, tungsten, uranium, and others, resulting in hydrothermal vein deposits such as the famous tin mines of Cornwall, England, or the tin/tungsten deposits of Malaysia. In magmas of granitic composition, the late-stage fluids sometimes crystallize to form rocks known as

Green tourmaline on quartz from Minas Gerais, Brazil

Source: Photograph taken by author of specimen at the A. E. Seaman Mineral Museum.

granitic pegmatites, famous for gem minerals such as topaz, aquamarine, and tourmaline (see fifth photo), as well as strategic metals such as lithium, beryllium, and tantalum and rare earth elements so important to today's technology. Important pegmatite fields are located in Minas Gerais, Brazil, the Black Hills of South Dakota, Bernic Lake, Manitoba, and the northern areas of Pakistan and adjoining Afghanistan.

Minerals react differently to the different chemical environments provided by nature. In generally arid climates (e.g., southern Arizona and New Mexico), limestone appears resistant to erosion, forming protective caps on buttes and mesas, but in a more humid region (e.g., Guilin, China), a dramatic, karst topography has developed. This is a direct result of the instability of calcite (limestone's principal constituent) in an acidic (low pH) environment. In passing through air, rainwater dissolves carbon dioxide, forming carbonic acid, which promotes dissolution of the calcite. Many other minerals are also affected by changes in pH and/or oxidation potential. A classic example is the development of oxide zones on metal-bearing sulfide deposits. Above the water table, conditions are generally more oxidizing, and more

Azurite (blue) and malachite (green), two common secondary copper minerals from Bisbee, Arizona

Source: Photograph taken by author of specimen at the A. E. Seaman Mineral Museum.

reducing below it. Metals leached from sulfide minerals above the water table may recombine with available anions to form “secondary,” or supergene, minerals (e.g., sulfates, carbonates, phosphates, arsenates, etc.), depending on what anions are available (see sixth photo). Below the water table, the metals may recombine with reduced sulfur to form a zone of secondary enrichment, or high-grade ore. The rusty “iron hat” or gossan that often caps such deposits was an important indicator to early prospectors in the American Southwest that an ore body may lie beneath.

Minerals are also affected by changes in temperature and pressure and may recrystallize in the solid state to form new minerals that are more stable in the prevailing conditions. The same tectonic forces supplying the pressure driving the resulting metamorphism often form folded mountain chains such as the Appalachians, with rocks hosting garnet, kyanite, sillimanite, and other metamorphic minerals.

Minerals affect our everyday lives in more ways than we can imagine. Without them, we

would have no houses, cars, airplanes, or computers. Their supply and demand figures prominently in the global economy and geopolitical decision making, and their geographic distribution has determined the location of railroads, highways, and villages. As you read this final sentence, look around you and imagine what would be left in your surroundings were there no minerals.

MINING AND GEOGRAPHY

Mining is defined as the extraction and concentration of metallic and nonmetallic minerals for use in a variety of human activities. As a distinctively human pursuit, the extraction and use of resources from the surface of the Earth is essential for most industrial production and the provision of a wide variety of materials. Geographers have long examined mining activities, primarily by focusing on the distribution of resources, the expansion of mining activities, the development of technologies to extract elements from the Earth, and the environmental and social impacts of mining operations.

The Mining Frontier

According to the U.S. Geological Survey, more than 70 chemical elements and dozens of minerals are currently mined from more than 100 different types of deposits. According to the Raw Materials Group, in 2005, the value of global mining production was approximately \$800 billion, with metals accounting for roughly 27% of the total, industrial minerals and diamonds 7%, coal and uranium 52%, and crushed rock 14%. Of the many metals that are currently being mined around the planet, gold, iron, copper, nickel, zinc, and lead production account for more than 80% of all production. These metals are extracted primarily by large international mining corporations operating in numerous countries. In contrast, coal is extracted primarily within countries for domestic consumption and energy production.

Mining is inherently a geographic dilemma because many elements created by geologic

processes are unevenly distributed across the Earth. Moreover, concentrations of these elements that humanity has deemed important are often located in remote areas, far away from where they can be refined or will be incorporated into manufactured items. This dilemma forms one of the most important focal points for geographers as they have labored to identify the locations of these resources. Consequently, the frontier for mineral exploration has continually expanded over time. In addition, as new mining activities have been established along this frontier, they have led to the creation of many new social, economic, and political relationships among different places and societies.

Since antiquity, miners have explored and exploited hillsides, streambeds, and subterranean depths in pursuit of the rarest and most valuable minerals, such as gold, silver, copper, and diamonds. During the earliest human civilizations in Asia, Africa, Latin America, and Europe, the frontiers for minerals such as gold, silver, and copper were generally located within the economic and political domains of each society and formed the basis of most international trading networks. By the 15th century, the mining frontier rapidly expanded as the European powers conquered the Western Hemisphere, Southeast Asia, and several parts of Africa. Alongside this expansion of the mining frontier, many European powers also established colonial mining settlements and forced local populations to work in their mines. Since then, a series of discoveries of rich mineral deposits in places such as California, Alaska, Peru, and Central Asia have incorporated ever more remote areas into the mining frontier. Along this frontier, new cities and mining settlements have rapidly appeared, often as part of far-flung empires or as part of growing nation-states.

Mining Technologies

The productive capacity of mining operations is a function of the relative concentration and quantity of a particular element that is being exploited and the technologies used to extract it. Researchers have illustrated that for many millennia, human labor (often in the form of brutal slavery) and rudimentary tools constituted most mining

A 20-foot-diameter ball mill rotates at a copper mine's underground processing facility in Chile. This process breaks copper-bearing ore from golf-ball-sized pieces into dust. Chile's economy is buoyed by Chinese demand for its copper, much of it mined by state-owned Chilean companies.

Source: Michael Fuller/iStockphoto.

technologies. Since then, innovations in technologies such as geographic information systems, heavy machinery, and explosives have dramatically increased the productive capacity of large-scale mines and have gradually reduced the role of human labor in extractive activities. These new technologies are critically important because many of the richest and most readily accessible deposits of valuable minerals have been exhausted and because they allow mining companies to extract very small concentrations of elements from very large volumes of earth. As these new types of mining are very expensive, the mining sector has increasingly become dominated by corporations with access to large quantities of capital, the most sophisticated technologies, and global transportation and production systems.

Geographers have increasingly focused their attention on these global mining production systems through the use of new spatial technologies as well as research focused on economic globalization, shifting patterns of employment and production, commodity networks, and the spread of large transnational mining corporations to new regions.

Mining and the Environment

The mining sector has historically been one of the dirtiest industries and is also the subject of contentious debates about the role of mining in fostering sustainable economic development. Abandoned mining installations are the source of

environmental problems such as toxic acid mine drainage. In addition, because large companies now engage in vast, open-pit mining operations that deploy new and untested technologies such as cyanide heap leaching and deep-water tailings disposal, many researchers have increasingly focused their attention on the environmental legacies of mining as well as the potential threats that these activities pose for fragile ecosystems and human health. Furthermore, because many transnational mining operations are now being located at the most remote fringes of the mining frontier, and often where human populations are impoverished, their role in fostering economic and sustainable development has been a topic of debate across many disciplines. This issue, which is often referred to as the “resource curse” hypothesis, has become even more relevant since the mining sector expanded rapidly at the end of the 20th century.

Recent geographic research focusing on the human and environmental dimensions of mining often draws on development studies or cultural and political ecology approaches to understand the multiscale and complex social and environmental transformations that mining activities are initiating. In addition, critical geographic research has begun to address the role of mining in local struggles over natural resources, the formation of social movements, and social change.

MITCHELL, DON (1961–)

Don Mitchell is well known for his significant contributions to the field of cultural geography. Mitchell received his PhD from Rutgers University in 1992 and is Distinguished Professor of Geography at Syracuse University. He is a recipient of numerous awards, including a MacArthur Award and Fulbright and Guggenheim fellowships. His scholarship revolves around investigating the way people think and live their lives in particular places, and the associated networks of power that those relationships entail. He focuses on issues related to migrant labor and agricultural landscapes, urban public spaces, the homeless and hungry, and other marginal populations in U.S. cities.

Mitchell approaches ideas and theories of culture through a broadly Marxist and radical framework, exposing the various ways “culture” is revealed in the landscape through social struggles and the exercise of power. Mitchell argues that scholarship and political commitment cannot be divorced, emphasizing a decidedly social justice approach to geography. He has authored numerous articles and three books that examine the various meanings of public space, particularly as it relates to controlling marginalized people and public protesters. Much of this work emphasizes the relationship between law, rights, and public space. His volume *The Lie of the Land*, concerning agriculture in California, emphasized the role of labor in the region’s landscapes. His textbook *Cultural Geography: A Critical Introduction* is seen by many as the starting point for university students interested in understanding the transformation of cultural geography that has occurred in the past two decades. He has also written extensively about struggles over the meaning and control of urban public spaces.

Mitchell is also the founder and director of The People’s Geography Project, which brings the insights of critical contemporary geography to lay audiences, activists, and teachers. This effort, combined with his work with advocates addressing hunger in the Syracuse area, has evolved into the Community Geography Initiative. Community geography uses geographic information systems (GIS) and spatial analyses to create maps

that support community advocacy and organizing, and it serves as a resource for nonprofit social service agencies that would like to use GIS to address community concerns but lack the resources or technical capacity.

MIXED FARMING

Mixed farming includes both arable and livestock farming. However, it has many forms depending on different and interrelated factors including the level of technology available, the relative financial rewards for crops and livestock, farmers' perceptions of risk and their attitudes about farming (e.g., organic/nonorganic), political conditions, the national and international policies of governments, climatic and other physical variables, and the availability of labor.

All these factors, and others, may have effects at different scales. For example, individual fields on a farm may be mixed; a farm may have some fields that are arable and some in pasture for livestock; a region may have some farms that specialize in cereals and others that specialize in livestock. These systems are not static but may change over time in response to one or several of the factors affecting farming. The following cases exemplify the effects of scale and the factors affecting farming.

Case Studies

In parts of Mediterranean Europe, fields may be found with a mix of tree crops, with cereals beneath and in some cases livestock turned onto fodder cereals. The first photo shows a field with sheep turned onto cereal beneath fig trees in Eastern Mallorca, Spain. Formerly, this was common, especially with almonds as the tree crop. Although such mixed fields may still be seen, greater rewards from mass tourism over the past 30 years have reduced interest in agriculture, particularly among younger people who have migrated or who commute to coastal communities with their tourist industries and "improved" lifestyles. Care of trees and cultivation of crops beneath have declined, and many fields have been left to grazing of ruderal vegetation (seminatural plants that have colonized) or have been abandoned. Changes in rewards from agriculture relative to other activities and changes in people's perceptions of lifestyles have affected mixed farming in this dry and agriculturally marginal area of Mallorca.

At the farm scale, mixed farming in the United Kingdom referred to a farm with arable fields and pasture fields for livestock—dairy or beef cows or sheep. Enterprises were seen as interrelated; for example, manures were used as fertilizer on arable fields. Rotation of fields could be practiced; after a period in grass, a field could be ploughed for arable use, whereas arable fields could be put down to grass. This rotation helped maintain soil fertility and, in an era when pesticides and herbicides were uncommon, helped reduce disease and pests. Since World War II, in response to government initiatives and those of the European Community and its Common Agricultural Policy (CAP), the number of mixed farms has declined continuously. Subsidies encouraged specialization, so that in much of eastern England not only are farms specializing in cereals but also the region has a landscape dominated by cereals.

A region of Northern Ireland exemplifies the impacts on mixed farming from changes in the interacting factors affecting agriculture. In 1938, the United Kingdom as a whole was in an agricultural depression, and most food was imported, so there was no demand for specialized farming. At this time of low profitability, farmers spread their risk by practicing mixed farming. Farming in

A mixed field: sheep turned onto fodder cereal beneath fig trees, Eastern Mallorca, Spain

Source: Author.

Northern Ireland was mostly of low mechanization with use of horse-drawn implements. There was some need for feedstuffs to be produced on the farm for livestock, including oats for horses. There was little use of inorganic fertilizers, farmyard manure was used, and fields had rotations of arable crops and grass. Labor was plentiful and met the high labor demands of mixed farming; the lifestyle of families working together on their own farm was highly prized, as families had gained the right to own their small farm only at the end of the 19th century. Figure 1 shows the mix of arable and pasture land in 1938 in part of county Armagh.

By 1990, in contrast, almost all these factors had changed. The experience of World War II had encouraged the national government to promote more home production of food, a policy enhanced when in 1973 the United Kingdom joined the European Community and its CAP. In Northern Ireland, with its moist climate, damp soils, and

small fields and farms, specialization was not into cereals, as in Eastern England, but into grass and livestock. Grass production became more intensive with the use of slurry, rather than farmyard manure and artificial fertilizers. There was less use of rotations; instead, grass that became less productive was ploughed up and replaced. Grass species were changed to more productive rye grasses used directly as pasture or to produce two cuttings each year of silage (grass cut green, as opposed to dried hay, and stored for winter feed). Farming became more mechanized, tractors replaced horses, and there was no need for fields of oats. Supplementary feedstuffs for livestock were easily transported onto the farm. Although the family farm remains a prized possession, families are smaller, and young adults have moved to towns and what are perceived as higher-level occupations. The result of these changes is a decline in mixed farming and a landscape in which grass appears to be the only field cover (Figure 1).

Figure 1 Changed regional pattern of farming, County Armagh, Northern Ireland

An example of farming in Southern Africa: Maize or sorghum grown near to and stored in the settlement. Livestock, including goats, are also kept, and the surrounding country is a source of firewood and building materials.

Source: Author.

The examples from Mallorca and Northern Ireland show how changes in the interrelated factors affecting agriculture influence mixed farming. However, mixed farming has not disappeared. In the United Kingdom, there remain small farms where farmers believe that mixed farming can spread risk—if prices of one crop decline, then livestock or other crops may help protect the overall farm income. There are also farms of several thousand hectares that are mixed to make best use of differing land conditions and to achieve maximum profit. There are also new types of mixed farming. For example, some farmers manage areas of their land for environmental purposes, such as rehabilitation of old pastures or planting of new woodlands—encouraged by changes in the CAP. Farmers have also included fields of energy crops; in Northern Ireland, fields of short-rotation coppice willow may be found among pasture fields. Many farmers have diversified their activities to maintain or improve their income. Examples

include development of equine facilities and conversion of redundant farm buildings to small business parks—to produce what might be more properly called mixed enterprises rather than mixed farming.

There are more perspectives on mixed farming in Africa than in Northern Europe. In large parts of Southern Africa, agriculture is characterized by small plots of maize or other cereal and of vegetables, often near the house. Extensive livestock grazing occurs on the surrounding land, which is also used for gathering of firewood. The farming may contain elements of subsistence agriculture and of commercial agriculture. It is mixed farming but not as may be described in many conventional European or North American texts.

MOBILE GIS

Mobile GIS (geographic information systems) is an integrated software/hardware framework to allow users access to geospatial data and GIServices through mobile devices (e.g., iPhones, pocket PCs [personal computers], Smart phones, notebook computers, and personal digital assistants [PDAs]) via wired or wireless networks. There are two types of mobile GIS applications: *field-based GIS* and *location-based services* (LBSs). Field-based GIS focuses on GIS data collection, validation, and update in the field, such as adding or editing map features or changing the attribute tables in an existing GIS data set. Location-based services focus on business-oriented location management functions, such as navigation, street routing, finding a specific location, tracking a vehicle, and so on. The major differences between the field-based GIS and LBS are the data-editing capabilities. Most field-based GIS applications need to edit or change the original GIS data or modify feature attributes. LBS rarely changes original GIS data sets but rather uses them as background or reference maps for navigation or tracking purposes. Most field-based GIS software packages are cross-platform and independent of hardware devices, such as ESRI's ArcPAD and Mapinfo's MapXtend. On the other hand, LBS technologies focus on creating commercial value from location-based information, as does Google's mobile map on iPhone applications. Most LBS applications, such as GPS navigation systems and smart phones, are using proprietary operating

systems, which are not interoperable across different platforms.

This entry first describes the components and communication systems of mobile GIS. Next, it examines both LBS and field-based GIS applications and the limitations of mobile GIS. Last, this entry discusses the future directions of mobile GIS.

Components and Communication

The architecture of mobile GIS follows the concepts of client-server architecture as in traditional Internet GIS applications. Client-side mobile GIS components are the end-user hardware devices that display maps or provide analytical results of GIS operations. Server-side components provide comprehensive geospatial data and perform GIS operations based on a request from the client-side components. Between the client and the server, there are various types of communication networks (e.g., hardwired cable connections or wireless communications) to facilitate the exchange of geodata and services. There are six basic components of mobile GIS: (1) positioning systems, (2) mobile GIS receivers, (3) mobile GIS software, (4) a data synchronization and wireless communication component, (5) geospatial data, and (6) GIS content servers (Figure 1).

Mobile GIS can provide geospatial information and GPS coordinates for field-based personnel conducting remote-field (in situ) GIS tasks. To enable comprehensive mobile GIS, wireless communication is essential for connecting mobile GIS devices and GIS content servers. Recent progress in broadband wireless technology is the major momentum for the integration of mobile GIS and Internet GIS. The wireless service coverage (availability) and the bandwidth (speed) are the two key issues for wireless communication. There are many different wireless technologies, ranging from a walkie-talkie to high-speed WiMAX (worldwide interoperability for microwave access) to satellite phone systems. Based on the speed of data transfer, current wireless technologies can be categorized into two groups: narrowband wireless systems and broadband wireless systems. To communicate between mobile GIS and Internet GIS, broadband wireless technologies, such as

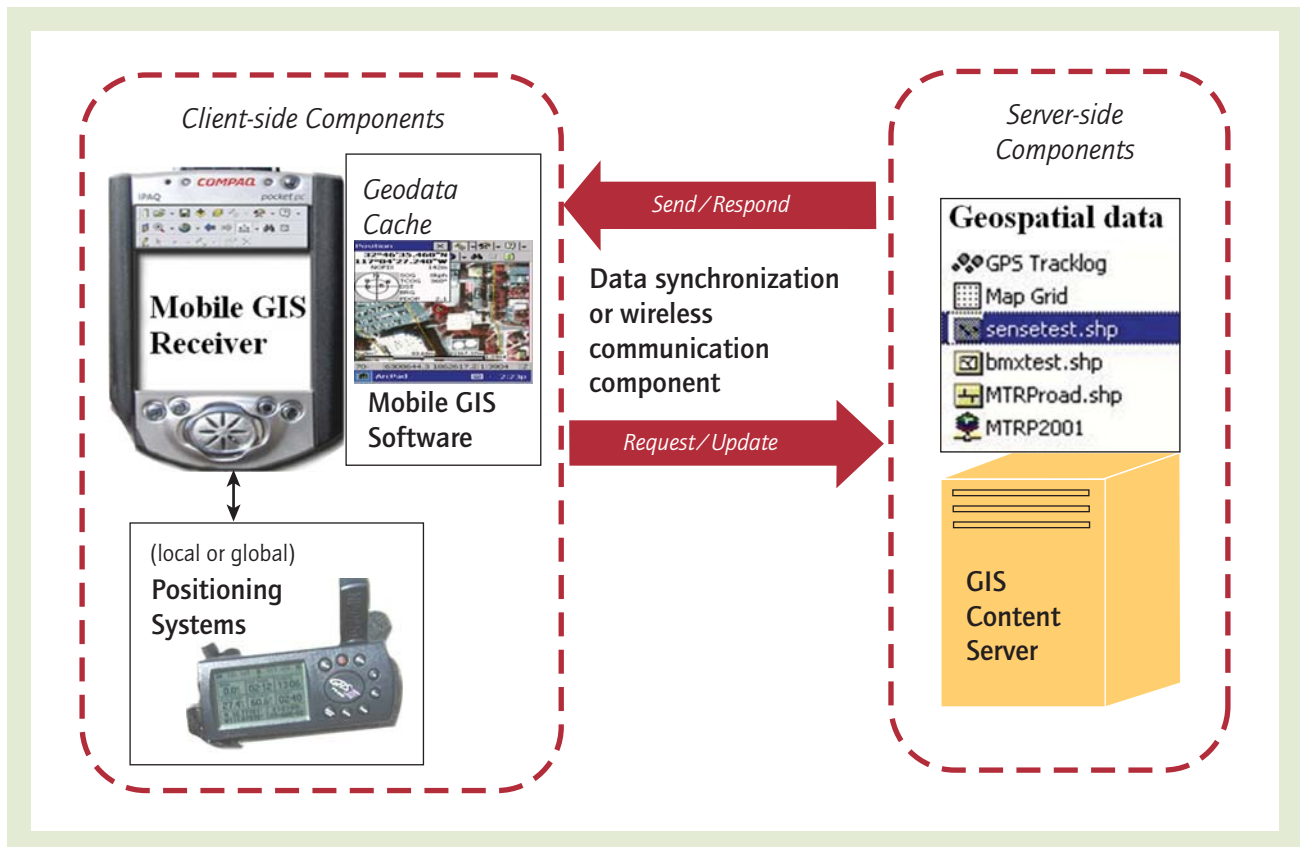

Figure 1 The architecture of mobile GIS

Source: Tsou, M. H. (2004). Integrated mobile GIS and wireless Internet map servers for environmental mapping and management [Special issue]. *Cartography & Geographic Information Science*, 31(3), 153–165.

Wi-Fi or WiMAX, are a better choice because most geospatial information and remote-sensing data are very large and complicated, which requires broadband wireless communication. The size of wireless coverage area is also an important criterion for mobile GIS applications.

Currently, there are three popular wireless communication systems: ad hoc systems, cellular phone systems, and Wi-Fi/WiMAX data network systems. The ad hoc wireless systems are custom designed for specific applications, such as direct satellite phone systems, General Mobile Radio Service (GMRS) for walkie-talkie devices, or ham radio communication. Usually, these systems are narrowband and localized for a small group of special users and require specialized user licenses. 3G and 4G mobile cellular phone communication systems can provide a good coverage area with a decent bandwidth communication. Cellular phone

systems can allow other wireless devices such as PDAs and pocket PCs to receive multimedia services (e.g., streaming audio and video on the devices). Most mobile GIS devices can use 3G or 4G cellular communication systems for collaborative work with Internet or Web-based GIS applications. Wi-Fi and WiMAX are the best communication systems for mobile GIS because they can provide very high-speed and stable Internet connections.

Location-Based Services

One important subdomain of mobile GIS is in LBSs. LBSs refer to a system that offers real-time updates about a location and its surrounding information. This information allows users to select a destination and to create the best route to

get there or to conduct business transactions. LBS systems and mobile devices have emerged as an important means of conducting business in a variety of fields. LBSs focus on business-oriented location management functions, such as navigation, street routing, finding a specific location, tracking a vehicle, and so on. Traditional desktop GIS cannot provide such real-time, portable, location-based information for end users.

Field-Based GIS

Traditionally, field-workers have to take a laptop computer with preloaded data when going into the field. There is no direct connection with office data systems, and field-workers have no way to know whether the data have been updated since they were last downloaded into the laptop. Lack of contact with the office also means that field data updated by the field-workers cannot be made immediately available in the office database. This time delay is not acceptable for time-critical applications such as utility repairs, facility security, and emergency responses. Furthermore, managing and maintaining the synchronization of data and software between the field computer and office computers can be costly and complex. With mobile GIS, coupled with GPS (global positioning systems), there is a direct connection between the field-worker's mobile devices and the database in the server. Any update in the office database will be instantly transmitted to the field-workers, and vice versa. Field-based GIS have been adopted in many application areas, such as facility management, land use management, and emergency and rescue responses.

Limitations

Current mobile GIS lack spatial analysis and GIS modeling functions. Many emergency tasks and disaster management works will need advanced GIS analysis functions that require significant computing power and computer memory. Most mobile GIS devices are tiny and only have very limited computing capability. The preprocessing and postprocessing time for spatial analysis and remote-sensing images might prevent the adoption of mobile GIS for real-time response tasks

due to the hardware limitations. One possible solution is to send the complicated GIS model and spatial functions via the Internet to remote GIS engine services with a comprehensive geospatial cyberinfrastructure. The analysis results will then be sent back to the mobile GIS devices via the network.

Another limitation of mobile GIS is the lack of alternative display methods. Since most mobile GIS devices are small and fragile, emergency responders and managers might be reluctant to use small screens on pocket PC or cellular phones to share their maps with others. One possible alternative is to project maps directly from mobile GIS devices on a white wall or another type of a shared display. It would also be very useful if users could print paper maps directly from their mobile GIS devices via wireless portable printers or from a built-in printer inside a pocket PC or a notebook computer.

Future Directions

Mobile GIS is a very promising field, with a considerable demand for its technology and products from field-based workers, LBS, and GIS vendors. With the development of new mobile GIS technologies and mobile devices (e.g., iPhones, iPod touch, Google's Android platform, Blackberry, and Microsoft Smart Phone systems), many new applications (e.g., homeland security, emergency rescue, real-time environmental monitoring, virtual tour guides, wildfire management, vehicle navigation services) will be possible. Mobile GIS will be more and more ubiquitous and essential in our daily lives and activities.

MOBILITY

The concept of mobility brings together human characteristics of identity and power with a dynamic understanding of space, place, and change. Different mobilities are shaped by different geographies, by the varying types of spaces people move through (e.g., public or private, urban or rural, real or virtual), and by a range of factors from cultural norms to modern security and immigration controls. Further influences include access to the means of mobility, be they cars, computers, bikes, or pavements, and the varying ability to be mobile, based on age, sex, body type, and other components of identity. Mobility is constructed in relationship to relative immobility, or what are sometimes termed *moorings*, locations where mobility appears temporarily abated. Yet as absolute immobility is all but impossible, the mobility concept proposes that everyone and everything is mobile and that it is matters of scale, difference in speed, and variation in direction that create appearances of relative immobilities. Mobility can also be used to assess the impact of modern telecommunication and computer technologies on sociospatial relations, such as changing labor practices through

which the mobile office makes almost any location a potential workplace, and, in a more metaphorical context, to explore the virtual experiences of moving through spaces via the Internet, videogames, television, and film.

Mobility scholars challenge traditional social science theories that often assume sedentary sociospatial relations and being stationary as the usual condition of life. In contrast, the mobility lens understands motion to be both normal and meaningful, not merely a temporary condition that occurs when moving between fixed locations. The concept thus challenges static understandings of space and spatial relationships, often defined by delimited areas such as nations, regions, cities, and homes. Consequently, where past geographical studies commonly analyzed such places as isolated entities, theories of mobility understand space as interconnected networks through which flows of people, goods, technologies, information, and images move. This constant movement forms the basis for analyses of mobility yet does not deny that there are material aspects to life. Mobility is not ethereal. It is tied to places and exhibited through physical forms. For example, cars allow the function of mobility, but garages, repair shops, streets, and highways are the relatively immobile moorings necessary for mobility to be enacted. Similarly, an airport may seem immobile, but passengers, baggage, workers, inspectors, security guards, capital, goods, vehicles, and so on, continuously move through its spaces. Even the airport buildings and runways, if looked at through a greater temporal lens, are mobile as they are remodeled, extended, damaged, and repaired. Envisioning spatial relations through a lens of mobility thus reformulates ideas of space, scale, and time.

Mobility is relational and differs from person to person. It matters who is doing the moving, where, when, how, and why. Immigrants, diaspora populations, and international tourists experience mobility differently from commuters, nomadic peoples, or prisoners. Men and women experience moving through space differently, as do young and old, people of different social classes, races, ethnicities, and nationalities. For example, if an adult and a child are traveling together, the child, while involved in the same movement, does not experience the same sense of

Family members out for a bike ride. The experience of mobility varies between adult and child and between men and women; thus, even when family members are traveling together on bicycles, their experiences of mobility will differ.

mobility, and thus, the two individuals understand and practice very different mobilities. Similarly, mobility in contemporary European space is very different for an academic with a British passport going to a conference than it is for an Ethiopian economic migrant moving through the illicit spaces of the underground economy. Encountering difference is often an aspect of mobility. Travel writings and accounts of foreign journeys commonly romanticize unfettered movement through the places of otherness, whereas vacations, exile, and emigration are experiences of difference that generate disparate mobilities.

Theories of mobility propose that traveling is in itself meaningful. Travel is not merely the act of getting from one location to another, but how people move and what they do while moving are critical to understanding the networks and relationships of contemporary society. There is significance in the journey between its start and end points. Traveling by car (automobility) produces a different experience from traveling in another manner. The social interactions, duties, habits, and countless aspects of a journey are further changed by who is traveling, where they are traveling, what kind of spaces are being moved through, and why the journey is occurring, among other factors. How a person behaves in a car is usually different from the social interactions experienced in rail, bus, boat, or air travel and different again from walking, cycling, or running. One travels differently with children or pets than when alone; experiences travel differently when with different family members, friends, colleagues, or clients; and is differently mobile due to age, bodily ability, or other factor. Some critics have proposed that analysts favor assessment of certain forms of travel over others, for example, the experiences of global air travel by affluent individuals from Western nations, and thus narrow the definition of mobility to that which is avail-

able and accessible to certain small sections of the population. Others demand that routine activities, such as going to the grocery store, driving to work, or walking to a friend's house are everyday mobilities worth exploring.

Mobility is always socially unequal. The right to movement is variable, and people have different abilities and opportunities to move. The gendering of spaces, for example, women-only carriages on Japanese trains, can be understood as changing the mobility of women in relation to men; fear of crime may reduce the mobility of the elderly and children in relation to young adults;

religious beliefs may limit mobility for some and increase it for others within and between specific locations, such as reserving areas within temples for specific individuals or certain routes for pilgrims. Space can also be understood to be racialized, and in certain contexts racial and ethnic identities may aid or hinder mobility. In the 19th-century United States, African Americans experienced very different mobilities as they traveled through slave and free states, and Native Americans saw their nomadic lifestyles curtailed as they were immobilized on reservations. Synchronously, white Americans were moving west on railroads and in wagon trains, experiencing greater mobility. The meanings of different mobilities are, therefore, produced from different contexts, agencies, experiences, and practices.

MODELS AND MODELING

A model is an idealized, abstract, and structured representation of real phenomena. Models may manifest as verbal descriptions, physical objects, diagrams, maps, mathematical formulas, and computer programs. Representation of complex dynamic systems increasingly involves computer simulation of alternative model outcomes based on specified input parameters, variables, and relationships. These models link a system's structure to behavior for the purpose of changing a structure to improve behavior. The purpose of a model provides the basis on which its utility must be judged, as all models are by definition simplifications of reality. This entry discusses the modeling process, the assessment of model utility, and the differences among several common modeling paradigms.

The Modeling Process

Human beings implicitly model all the time. Routine decisions in everyday life are guided by elaborate and yet incomplete mental models of the tasks at hand. For example, a person driving a car associates a yellow light with the need to slow down (or hurry through the intersection). In making this association, the person's mental model simulates, or translates the perception of a yellow signal into, a decision of whether to slow down or hurry up, depending on rapid evaluation of one's position relative to the intersection. This decision is carried into action by an adjustment of foot pressure on the accelerator and brake pedals. This sequence of information, perceived and acted on by a person's mental model, is one experienced many times over in a given day. In this way, mental models may be largely subconscious but yet represent intricate webs of understanding that guide (and misguide) human behavior.

Formal modeling enables explicit testing of underlying assumptions that humans carry in the form of mental models. One strategy for making models explicit is to slow down one's thought to become aware of the implicit mental models that simulate both immediate and longer-term scenarios of the system of concern. Group modeling experiences benefit from the process of slowing, exposing, and challenging implicit mental models.

Figure 1 The modeling process in context. The iterative process of modeling creates an experimental learning feedback loop in the context of the real world.

Source: Adapted from Sterman, J. (2000). *Business dynamics: Systems thinking and modeling for a complex world*. New York: McGraw-Hill.

The process of making mental models at least partially explicit—explaining ideas to others in conversation or writing, drawing, or encoding them in computer models—exposes the limitations of their scope, based as they are in an individual’s personal experience. As mental models are formalized, the explicit model becomes an artifact readily shared with others, while the implicit mental models continue to update based on information feedback from both the model and the real worlds.

In a dynamic modeling process (Figure 1), observations and decision rules may be input as data and assumptions into computer models, and simulated output may inform policies for making decisions. As mental models are updated with observations of both the real and the model worlds, they translate into updated decision rules or heuristics that shape the decisions that manifest as actions in the real world. The reflexive relationship between mental models and the

process of modeling reveals it to be at once an art and a science. The art of modeling includes the role of intuition in problem formulation and hypothesis development, as revealed by the selection of relevant variables for the system of interest. The science of modeling centers on a consistent, reproducible methodology for testing theory by comparing simulated output with observed data. Steps of the modeling process generally include the following:

1. Problem formulation and boundary setting
2. Mapping a dynamic hypothesis as a diagram of causal relationships and feedback
3. Computer model formulation as mathematical expressions and/or algorithms
4. Boundary testing and calibration of model to observed data
5. Policy analysis and scenario simulation

Figure 2 APT dimensions of model utility. Dimensions of authenticity, parsimony, and transparency (APT) help assess the utility of a model relative to its purpose.

Source: Author.

Although the above sequence implies that the modeling process begins with problem formulation, the process may be entered at any stage and is iterative such that the understanding from policy analysis (Step 5) leads back to a reconsideration of the problem as formulated. This “problem of problem formulation” reinforces the value of modeling in moving through new layers of understanding for the system of concern. Because the process of modeling itself is a source of insight, experienced modelers document expectations and results throughout their experiments in these virtual laboratories. This documentation enables utility from the modeling process to be assessed separately from the model *per se*.

Model Utility

The *authenticity* of a model may be assessed in multiple ways—by comparing simulated results with empirical observations and testing whether the model is consistent with the hypothesis articulated *a priori*. While no model will fully represent reality, modelers and decision makers will assess

how plausible the model results seem on the basis of their prior assumptions about the system of concern. Because models are abstractions of reality, regardless of how intricate, much insight may be gleaned from *parsimony*, the art of leaving things out. The principle of parsimony is that models should be as simple as possible but no simpler. One way to assess parsimony is to measure the number of elements and relationships therein. Models with fewer interacting elements have more explanatory power than models that emphasize detail and complexity over dynamic essence. Model utility is also revealed by its relative *transparency*: Can the model be understood by a broad audience? Are the feedback mechanisms driving system behavior clearly documented? Models that lack transparency have a limited utility beyond the experts who interact with them.

The form of a model affects its utility. Physical models range from scaled-down structures such as miniature train sets to scaled-up representations of molecular structures based on connections between core elements. In geomorphology,

scaled-down flumes function as models of water flow through topographically variable sedimentary conditions. Graphical models range from simple diagrams showing elements and relationships (such as those in Figures 1 and 2) to elaborate maps that reveal spatial patterns. Maps of both the cartographic and the cognitive kind may be considered models in the broad sense, models as representations of reality. As for maps, scale matters for models—small-scale systems may be represented with linear models, while nonlinear, large-scale systems remain largely terra incognita.

Modeling Paradigms

Statistical models align with the inductive approach to the scientific method, whereby one draws conclusions based on available evidence. In practice, this is often iterative, such that initial inferences are first drawn with the aid of descriptive statistics, then formal models are formulated to fit part of the data (the training set) and predict another part (the validation set). However, an iterative approach in generating statistical models is problematic in that the identification of variables to include in a statistical model tends to be based largely on the data available, de-emphasizing the role of prior theory, the *a priori*, in shaping model form. Moreover, inference from observation obscures the role processes that are not observable. Reliance on observed data may bias the analysis toward including some things and leaving others out.

In contrast to statistical models, analytical forms of mathematical models are frequently used to develop theory for the system of concern. Newton's $F = ma$ and Einstein's $E = mc^2$ symbolize (in both the literal and the figurative sense) the utility of simple mathematical models for comprehending a wide range of phenomena in the universe. Analytical models tend to describe the average or aggregate behavior of a system, in that they merge individual variations to look for the essence and eliminate the noise. Differential equation models treat processes as continuous in time rather than discrete. This Newtonian worldview is increasingly challenged by suggestions that discrete mathematics is not only more pragmatic from a computational perspective but may more accurately reflect what's going on in the "real world."

The analytical approach using differential equations has advantages in transparency, due to the ability to convey simplified representations of real-world systems through calculus and its approximation on the computer. Simulation software that represents integrals as "stocks" and differentials as "flows" over time has enabled more combinations of ordinary differential equations than may be handled analytically.

Stock-and-flow models based on differential equations emphasize the dynamics of the system more than the spatial patterns created. However, a number of processes warrant explicit spatial representation, such as urban growth and climate change. When adding the spatial dimension to a dynamic model, challenges emerge with respect to the choice of spatial scale and extent. Such choices vary depending on whether raster or vector GIS (geographic information system) data are employed to calibrate the model or whether an abstract representation of space is adequate. Cellular automata are a form of abstract, spatially explicit models that rely on locally induced, memory-less state changes. Automata are discrete units arrayed in space (usually one dimensional or two dimensional) such that each automaton has a fixed number of neighbors with discrete states (e.g., on/off). The state of the individual automaton depends on local rules, conditional on its own state and the state of its neighbors. From a few simple rules, a variety of patterns can emerge. The simplicity of cellular automata provides a benefit of transparency; all one needs is to describe the rule that is in operation, which is especially easy as more students become trained in the Boolean logic that underlies computational systems. The cost of this simplicity is the strictly local behavior and lack of memory, such that cellular automata become more abstract explorations of possible phenomena than any sort of real-world analog.

The advent of object-oriented programming has enabled the development of software for constructing agent- or individual-based dynamic computer models. Object orientation enables individual agents or decision-making units to operate independently and interact with each other. Like cellular automata, agents use rules for decision making. Unlike cellular automata, agents may have memory and may be mobile and interact in non-Euclidean spaces such as social or

Figure 3 Mixing model paradigms. Distinct model paradigms such as stock-flow models, agent models, and GIS may be integrated with the available software.

Source: Author.

structural networks. The flexibility of the agent-based framework has triggered a broad interest in the social sciences, and individual-based models have been popular in ecology for some time. Agent-based models are able to accommodate a variety of scales and to capture a wide range of heterogeneous individual behavior. Such diversity appeals more broadly to the humanistic side of the social sciences, which has historically been reluctant to embrace highly aggregate and generalized statistical or analytical approaches. Moreover, the flexibility allows for the development of theories that incorporate individual everyday heuristics and examine how such individual behavior produces aggregate patterns. Critics of agent-based modeling emphasize the computational and conceptual challenges of trying to represent too much detail. Opening the door to greater flexibility puts a greater onus on the

modeler to fully think through the problem at hand and abstract accordingly. Because agent-based approaches are still in their infancy, limited guidance is available in the form of established methodologies for model building and verification.

Spatially extended models may couple cellular automata with stock-and-flow models to enable the dynamic model to be replicated for each individual cell of a grid, often corresponding with raster data for input. An abstract notion of space is used in many agent-based models as well, and further efforts are under way to integrate agent-based models with GIS. Figure 3 demonstrates how different modeling paradigms (GIS, stock-flow, and agent) may be combined using the available software packages. Here, a stock-and-flow representation of a continuous process is replicated spatially, embedding dynamic memory into a cellular automata framework where each cell interfaces with

information from the neighboring cells. Computational feasibility has become less of a constraint in choosing which model paradigms to employ, leaving many modelers with their own expertise as the determining constraint, though increased availability of multiparadigm modeling software helps to minimize paradigmatic bias and encourage cross-disciplinary collaboration.

MODERNITY

The term *modernity* refers to a set of political, economic, social, and cultural processes usually traced back to forms of knowledge and practice that emerged in Europe around the 16th through the 18th centuries, a period often termed the *Enlightenment*. The philosophies associated with the Enlightenment have been much debated and modified over the centuries, but their central principles of the primacy of reason and the autonomy of the individual continue to underpin dominant forms of social order in today's global context.

Typically implied in the concept of modernity are a sense of rupture with the past and tradition and a sense of progress toward a society governed by greater rationality, justice, and truth. Many scholars challenge these assumptions, highlighting modernity's "dark side," including the projects of colonialism in the 19th century, which were central to the definition of a European identity. They also question the universalism and Eurocentrism of dominant theories of modernity, arguing for a notion of multiple modernities as more productive in understanding the world's diverse forms of social order and development, especially within the Third World. In addition, contemporary debates on modernity address the question of whether recent broad social shifts, associated particularly with processes of globalization and the concomitant proliferation of new forms of knowledge, have in fact ushered in a distinctively new era. This process is central to understanding the geographies of the modern age, including the Enlightenment, technological innovation, colonialism, industrialization, and urbanization.

The Roots of Modernity

As with any historical era, the Enlightenment cannot be bounded definitively by particular years, or even centuries. The ideas that mark the Enlightenment as a distinctively new period could be said to have emerged anywhere between the 16th and 18th centuries, through the work of scholars from Francis Bacon, Thomas Hobbes, and John Locke in the 16th and 17th centuries to Denis Diderot, Voltaire, and David Hume in the 18th century. The paradigm of Enlightenment philosophy that emerged from these and other diversely situated and positioned writers is characterized by an emphasis on the principles of rationality, empiricism, universalism, progress, individualism, freedom, and secularism.

The emphasis on scientific reasoning in Enlightenment philosophies constituted a clear move away from the Church and forms of knowledge established by religious authorities. The world was to be known through experience and critical examination rather than mythical, mystical, or religious explanations. Traditional worldviews thus became associated with oppressive superstition, irrationality, and prejudice. In the narratives

of modernity that spring from Enlightenment ideals, and even those that explore alternative approaches to modernity, this idea of a break with tradition remains central. While the latter is typically associated with the ignorance—or sometimes, more charitably, “innocence”—of the past, the modern worldview is seen to be better, given its future-oriented, progressive state, enlightened by reason.

Central to this positioning of reason as the most superior human attribute is the notion of the independent self. Selfhood continues to occupy a pivotal position in ideas of contemporary modernity, particularly in Western cultures; not just the self as an entity, but specifically the freedom and autonomy of that self, are of primary importance in both Enlightenment thinking and dominant narratives of contemporary modernity. Human agency is central to understanding the modern social order and what it means to be a participant in it. Enlightenment thinkers were by no means the first to emphasize these aspects of the self, much less to develop the notion of an independent self, but the developments of scientific empiricism and analysis during the 17th and 18th centuries, particularly in Britain, lent a distinctly new impetus to these debates. The idea of the individual as an autonomous agent has become arguably the most defining aspect of modernity and has intensified through the democratic and capitalist processes that are globally dominant today.

Newness and Progress

Tradition is by no means synonymous with the past, but the two are often linked together to constitute an “other” against which modernity is defined. The idea of modernity therefore contains within it a strong element of newness and difference from the past. In this sense, each new era may lay claim to a modern identity. The 18th century, however, saw a development of this meaning such that modernity came to describe not just novelty but also improvement. The intellectual endeavor of this period was significant in its orientation to the future and its positioning of human beings as the agents, rather than simply the objects, of history. Human beings were reimagined as autonomous actors, creating a more ordered and equitable world.

The notion of progress thus became a fundamental characteristic of modernity. The liberation of all humans from ignorance, myth and superstition, poverty, and the arbitrary exercise of power was to be gained through turning to reason as the way to know and organize the world. This notion still holds significant sway today, illustrated, for example, by the power invested in science in dominant contemporary discourses. A teleological perspective is built into this understanding of modernity, in the belief that there is one universally right and true way of being, knowing, and doing and that all societies should aspire to the same basic ideals. This perspective and its implications have been manifested in numerous “projects of modernity.” These include Europe’s imperialist and colonial dominations, which reached a peak in the 19th century, and various modernization projects through the mid 20th century aimed at developing Third World countries according to the model of the West.

By constructing the traditional customs and practices of non-Western societies as static, backward, and ignorant, the authors of modernity and modernization projects simultaneously construct themselves as active, progressive, and having superior knowledge. They are thus saviors, fulfilling their moral duty to rescue primitive peoples by showing them the truth. A notion of “self” and “other” can therefore be seen to underpin the notion of modernity, which positions non-Western people in opposition to the ideals of modernity and its attendant principles of the betterment of humanity.

The opposition that has been set up between modernity and tradition in this way has been shown to be problematic. Traditional practices are neither as unchanging nor as oppressive as this binary view assumes, while the structures and practices of modernity have not fulfilled its vision of emancipation and empowerment of all human beings. On the contrary, the global modern age has been realized through numerous large-scale acts of oppression and violence, and influential theorists describe this era as one characterized by increased control and regulation, weakened social ties, and greater risk and uncertainty. The Enlightenment model of modernity as the primary, or sole, means of enabling human flourishing has been challenged, particularly by poststructural

theorists. Scholars working within the framework of poststructuralism and allied more specifically with feminist and postcolonial approaches have been particularly active in highlighting the Eurocentrism and masculinism of modernity. They have thus proffered alternative readings of the projects of modernity, while also identifying and envisioning multiple new ways of being modern in the present and future.

Multiple Modernities

The argument for a recognition of multiple modernities rejects a paradigm of modernity as a necessarily convergent set of processes or the singular end point of those processes. Instead, it advocates an understanding of the world and history as the story of many different cultural programs that are continually being shaped and reshaped. This view refuses a conflation of modernization with Westernization. It emphasizes the fact that although the Western trajectory of development has been globally influential, indeed dominant, it should be understood as one deeply contextual version—a particular set of values, institutions, everyday practices, and discourses—of what it means to be modern. This understanding rejects the universalism of a teleological model and opens up the possibility of appreciating the cultural variety in experiences and productions of modernity.

This approach has implications for many groups who do not fit the dominant model, which has been criticized for its “aculturalism” and gender blindness. Postcolonial scholars point to the importance of power relationships between the West and developing countries, which may have been instigated centuries ago through projects of colonialism but which are no less relevant in understanding today’s globalized economies, cultures, and politics. While the Western model of modernity must be contextualized as one particular evolution, the constantly shifting connections between Western and other countries also require a relational approach to understanding contemporary modernity. This differs from earlier models in that the West can no longer be defined as progressive as opposed to the stagnant cultures of the colonial other. Rather, multiple cultures, including those of the West, can be seen to be

embedded in a range of intersecting and overlapping sociopolitical processes.

In a similar vein, feminist theorists have pointed to the many binary oppositions and power structures implied in discourses based on Enlightenment philosophies, for example, nature/culture, private/public, traditional/modern, past/future, and emotion/reason. The first of each of these is typically, if implicitly, gendered female and devalued in the forward-looking projects of modernity. Revaluing these dimensions of social life is key, such theorists argue, to appreciating the multiple, and often contrasting and contradictory, modes through which modern life is shaped. This work builds on the assertion by feminist and other scholars that all knowledge should be recognized as partial and situated in particular times and places. This is especially true of those forms of knowledge that have become so embedded in the collective unconscious that they are no longer recognized as constructed rather than “natural.”

A New Social Order

A large body of contemporary work addresses the question of whether our times are in fact more usefully understood as a new era than simply as a continuation of a model based on Enlightenment thinking. This notion suggests that there has been a rupture with modernity significant enough to shape a new social order structured through novel values, politics, and ideals and is perhaps most evident in postmodern schools of thought. These take as their central premise the idea that “grand narratives” purporting to explain the world should be dismantled, since in a world characterized more by diversity, multiplicity, and fragmentation than any form of order, there can be no absolute truths.

There is, however, a strong counterargument that despite the plurality of modernities and the newness of our global and technological age, modernity has not truly come to an end or been surpassed. Rather, the social order that is termed *modernity* has been extended and intensified, particularly through the increased reflexivity of institutions and individuals. This reflexivity, or the continual interrogation and revision of all kinds of social phenomena, is itself produced through a proliferation of new forms of knowledge and a concomitant, pervasive sense of uncertainty. This

has been described as living in a “risk society.” We thus live not in an age that has moved away from the forms of knowledge that constitute modernity but rather in a period of heightened or radicalized modernity, termed *late modernity* by theorists including the influential sociologist Anthony Giddens.

Finally, the French theorist Bruno Latour argues that notions of modernity depend on a nature/culture divide that cannot be truly achieved or sustained. The category of modernity therefore must be redefined to take account of the hybrid systems that structure our social worlds. Our age, according to Latour, is neither late modern nor postmodern—we have in fact never been modern.

MODERNIZATION THEORY

Of the various theories that seek to explain patterns of international development, and the lack of it, modernization theory is one of the most famous and certainly the most influential. Modernization theory for decades was the mainstream, orthodox approach to explaining development, and it was enormously important in the foreign policies of the United States and, to a lesser extent, other countries. The essential question that underpins modernization theory is whether or not countries in the developing world follow the historical trajectory set by the West (i.e., Western Europe, North America, and Japan). In this reading, development is likened to a race, with some countries and regions “ahead” and others “falling behind.”

Origins

The origins of modernization theory may be said to lie with the famous sociologist Max Weber, who offered an idealist explanation of the origins of capitalism, particularly in his renowned book *The Protestant Ethic and the Spirit of Capitalism*. For Weber, capitalism could trace its start to the particular values held by Protestants in northern and northwestern Europe. It was no coincidence, he maintained, that Lutheran, Calvinist, Anglican, and Presbyterian countries were the first to industrialize, in contrast to the Catholic nations along the Mediterranean and in Eastern Europe. Protestantism, he held, offered a unique set of values that centered on delayed gratification, frugality, and saving. Material success in this world was held to be an indication (not a guarantee) of God’s grace and entry into heaven. For Protestants, work was an ethical obligation, and profit was a goal, not a sin. Thus, the Protestant ethic was instrumental in producing incipient capitalists.

The core of Weber’s view was that capitalism produced a sustained rationalization of social life. Rationalization is an ambiguous term and has been used in different ways, but essentially, it refers to the process of rendering the world intelligible by the imposition of an orderly, systematic, logical, and scientific worldview, in contrast to metaphysics. Indeed, rationality was at the core of

the Enlightenment project. Weber held that the process of rationalization fomented scientific discoveries and that secularization facilitated the pursuit of profit through an impersonal cost-benefit calculus. Politically, rationalization was manifested in the emergence of bureaucracies, which held to an explicit division of labor, specialized institutions, and lines of authority in which jobs were defined by standardized criteria, not the whims of the people who held them. Bureaucracies were necessary for the growth of laws that applied equally to all as well as to the protection of property rights. Economically, rationalization materialized through the market, in which profit maximization rewarded the innovative and productive and punished the incompetent. Weber asserted that Western rationalization was unique and was not possible in cultures dominated by Catholicism, Islam, Hinduism, or Confucianism.

Weber likened rationalization to an “iron cage” descending over the West, one that emerged from religion but ultimately squeezed religion into the irrational and inexplicable, robbing humanity of its soul. His idealist, pessimistic view thus contrasted sharply with the materialist, optimistic perspective put forth by Karl Marx.

Critics of Weber argued that his reading of the rise of capitalism was naive. Many capitalist institutions were evident in Catholic northern Italy, for example, long before the Industrial Revolution. Others criticize his privileging of religion as the source of social change, asserting that Protestantism was a response to, not a cause of, the new system of class and markets spreading throughout northwestern Europe.

The Parsonian Turn

Talcott Parsons, a professor of sociology at Harvard University, founder of the doctrine of structural functionalism and the first to translate *The Protestant Ethic* into English, played a decisive role in the growth and transformation of modernization theory, adapting it to the historical conditions of the mid 20th century. For Parsons, to be modern meant to be Western in terms of institutions, culture, economy, values, and governance: The terms were synonymous, and it was impossible to have one state without the other. Modernization in this light became an unabashed

celebration of capitalism—and the United States—during the height of the Cold War and a justification of American foreign policy toward states in the developing world.

The Parsonian modification of Weber’s project asserted that Third World countries should deliberately “follow” the path set forth by the United States and its allies, conscientiously adopting their culture, political systems, and markets. Over time, this view held, the developing world would evolve into something resembling the prosperous democracies of the West. What was called for was therefore gradual evolution, not rapid revolution (the latter being the siren call of communist parties everywhere). Thus, whereas Weber held that the rise of capitalism was contingent and specific to northern Europe, Parsonian modernization theory maintained that it was inevitable and universal.

Modernization theory posited that the process of rational economic development occurred simultaneously in the economic, cultural, and political domains. Economically, countries were theorized to move through a linear sequence of stages, such as via the Fischer-Price notion of agricultural, industrial, and postindustrial (service based) economies (although in reality, many countries become postindustrial without ever developing a large manufacturing sector).

The most famous explication of modernization theory was probably Walter Rostow’s exposition in *The Stages of Economic Growth: A Capitalist Manifesto*, published in 1960 with a title that explicitly played on Marx and Engel’s *Communist Manifesto*. Rostow, economic advisor to President John F. Kennedy, held that development was akin to an airplane taking off and proceeded through five distinct stages. The first, *traditional society*, was characterized by low standards of living and preindustrial technologies and life styles and was essentially static. The source of change in this context was necessarily exogenous. Such a stage characterized feudal Europe and characterizes the most economically backward parts of the world today (e.g., New Guinea, parts of sub-Saharan Africa, or Bhutan). The second stage, *preconditions for takeoff*, saw the development of primary-economic-sector activities such as plantations and mining. Countries that fit this description today include Mexico, Brazil, or

Indonesia. As society moved to the third stage, *takeoff*, it witnessed the creation of a physical infrastructure and the rise of social and economic elites open to social and economic change. Take-off itself was manifested through the growth of an export-oriented manufacturing sector as the country became increasingly internationalized, with foreign direct investment fueling much of the growth. As rising incomes generated a growing working class or middle class, domestic demand began to grow, and society became increasingly urbanized. China is perhaps the outstanding example of this stage at this moment in history, as are other rapidly growing Asian newly industrializing countries (NICs). The *drive to maturity*, the fourth stage, witnessed self-sustaining growth, labor unions, and an expanding commercial and industrial base as the division of labor became more refined and specialized. Current examples include South Korea and Taiwan. Finally, Rostow's nirvana, *high mass consumption*, was defined by an enormous middle class, high per capita disposable incomes, low degrees of poverty, and well-developed markets. Obvious examples would be the United States, Canada, Japan, and northwestern Europe.

Closely associated with this version of modernization is the process of spatial diffusion of ideas, technologies, institutions, and change. Modernization theory held that diffusion occurred at two intertwined scales. Internationally, modern characteristics diffused from the First to the Third World (never the other way) via organizations such as the World Bank, the International Monetary Fund, and transnational corporations, as well as through large-scale projects such as the Green Revolution. Within countries, modernity diffused from urban areas to rural ones; cities were viewed as dynamic, propulsive, forward-looking cores, and agrarian regions as inherently hidebound, static, and dominated by antimodern traditions. The implementation of growth pole theory in the 1950s and 1960s was an explicit expression of this ideology. In this light, given the faith that markets only created wealth, poverty was simply the result of the incomplete diffusion of markets, a state that could ultimately be overcome via the adoption of Western norms, technologies, and institutions. Modernization theory thus views uneven development as an incidental,

transient feature of capitalism, not an inevitable result.

Also closely associated with the economic dimensions of modernization theory was the program of population control. Indeed, the gains of rapid economic growth could easily be swallowed up by an expanding population, a view with Malthusian overtones. Modernization theorists, who also implicitly held an affinity for the demographic transition model and its stages, which so closely resembled Rostow's, advocated for birth control policies throughout the developing world. Programs such as the U.S. Agency for International Development (USAID), for example, posited population control and the resulting economic growth it was theorized to bring as a means of enhancing the appeal of the West against the siren call of communism in the wake of the Cuban Revolution of 1959.

In addition to the economic argument, modernization theory also proffered a cultural explanation. Tradition, in this view, was synonymous with economic backwardness and stagnation. Typically dominated by religion, premodern traditions were held to be irrational and detrimental to the process of market expansion and all the fruits it promised. Tradition, therefore, must be sacrificed on the altar of economic transformation. To be modern was to accept change—even rapid, bewildering, alienating change—as inevitable and as inherently good and necessary. That is, change was synonymous with progress. Examples of modernizationist interpretations of culture include David McClelland's analysis of textbooks throughout the developing world in the 1950s, in which he examined the degree to which they promoted entrepreneurial versus traditional values, and Robert Bellah's interpretation of Japan's modernization, which he asserted acquired a "Tokugawa spirit" that mimicked the Protestant ethic and propelled that country's entry into the industrial era. (Later Bellah changed his mind and renounced this view.)

Finally, modernization theory contained an explicitly political theorization, one that not only celebrated the West, and especially American values and institutions, but maintained that capitalism was a necessary precondition for the growth of democratic institutions. This line of thought held that only market-based societies generated

the wealth necessary to sustain a large middle class, which ensured the prevalence of civil liberties, including freedom of speech, assembly, and the press. (However, unlike later neoliberal theorists, modernization theory upheld a proper role for the state.) Unlike traditional societies, in which political power was centralized in the hands of a tiny elite, markets, theorists such as Samuel Huntington held, generated numerous, dispersed centers of power. Later, the famous economist Milton Friedman picked up this view in his assertion that capitalism and democracy always went hand in hand with one another: Economic freedoms and political freedoms were inevitably coupled.

Criticisms of Modernization Theory

Despite its numerous successes, modernization theory came under withering attack in the late 1960s and 1970s. Many pointed to its profoundly ethnocentric reading of culture, which posited the West as the only feasible or desirable model of economic growth, as well as its explicit universalization of American values. Indeed, modernization theorists could be maddeningly arrogant, condescending, and racist, as this quote by K. H. Silvert in 1962 illustrates:

There is something in the quality of the Latin American man and his culture which has made it difficult for him to be truly modern . . . which has made this part of the Western world so prone to excesses of scoundrels, so politically irrational in seeking economic growth, and so ready to reach for gimmicks. (Quoted in Valenzuela & Valenzuela, 1978, p. 542)

Indeed, by focusing only on the internal causes of poverty, specifically on ideas prevalent within a culture, modernization theorists were resolutely silent about the historical context of the societies they examined, ignoring the powerful role of colonialism and its legacy as well as the dynamics of the modern world system, which perpetuate, not reduce, uneven spatial and social development. Such a view ends up blaming the victims of poverty for their status.

As dependency and world-systems theories gained ground in the 1970s, modernization theory suffered a steady decline in popularity and was

quietly relegated to the background of development discourse. Dependency theorists pointed to the ways in which colonialism had left a highly uneven playing field among the world's states, creating a world economy that disadvantaged newly independent countries in the developing world. Interdependence, in this view, amounted to little more than exploitation. Far from eradicating poverty, markets reproduced it through the development of underdevelopment. In this view, developing countries do not simply lag behind the West. However, the rise of neoliberal thought in the 1980s and 1990s in some respects spelled a resurgence of modernization theory, as both schools of thought place enormous emphasis on the market as the primary mechanism driving social change and prosperity. There were differences, however, between modernization theory and neoliberalism, as the former did not universally advocate the privatization and deregulation favored by the latter.

MODIFIABLE AREAL UNIT PROBLEM

Often the area (or regional) level rather than the individual level is the target of inference in geographic and environmental science studies. The use of aggregated data sources while performing geographic (or spatially) related inquiries may well lead the researcher into an encounter with the modifiable areal unit problem (MAUP). Geographic analysis requires one to not only consider geographic area—the scale—but also the resolution of the data to be analyzed. The relationships between variables will change as the scale of measurement (resolution) changes. The relative size, scale, level of detail, or depth of penetration that characterizes an object or activity relates to the MAUP. This entry provides a cursory overview of the MAUP as it relates to geographic inquiry.

The outcome of two different geographic (or spatial) aggregations produce different degrees of within-area homogeneity; in geographic terms, the generic name for this is *modifiable areal unit problem*. The MAUP is common to all geographic (spatially) aggregated data. It consists of two interconnected parts. First, there is ambiguity about what constitutes the objects of spatial

study—identified as the scale and aggregation problem. Second, there are the implications this holds for the methods of analysis commonly applied to aggregated data. The MAUP requires the researcher to ask the questions of how to incorporate scale into methods of geographic analysis, how to determine and identify the operational scale of geographic phenomenon, how relationships between variables change as the resolution (scale of measurement) increases or decreases, and to what extent information on geographic relationships at one scale can be used to make inferences about relationships at other scales.

The term *modifiable* is used because neither the choice of the number of geographic units (the scale of the analysis) nor their particular arrangement (how partitioning or zoning is selected given the scale of analysis) is essential and any number of other choices can be made. The MAUP consists of two problems, one statistical and the other geographical, and it is often difficult to isolate one from the other. Statistically, the underlying concern is that the analyst may not be using the appropriate statistic for the problem being addressed. Geographically, the problem is intrinsic to the observation of the effects of different geographic (or spatial) aggregations and the subsequent interpretation of the patterns revealed by the different aggregations.

Hence, it is imperative that the MAUP be analyzed in the context of a well-defined model that identifies the different scale components (from the individual level upward) underlying the behavior of each of the variables.

MONEY, GEOGRAPHIES OF

Geography and money are no strangers to each other. A sizeable literature has documented the complex, often contradictory ways in which finance and space are shot through with each other. This topic finds its origins in an earlier sociology of money: Writers as diverse as Karl Marx, Max Weber, Émile Durkheim, and Georg Simmel were all concerned with the relations between modernity and commodification. Under industrial capitalism, for example, and the waves of urbanization it generated, cities arose as sites of new forms of social relations centered on money, leading to the widespread objectification of social relations in which everyone becomes a buyer or a seller. The researchers of the Chicago School of sociology, particularly Louis Wirth, were appalled by the predatory relations and culture of calculation that pervaded capitalist societies as ever more people were drawn into a money economy.

In its broadest sense, therefore, money was instrumental in the time-space compression of capitalism, the formation of the nation-state, and the rise of a global economy. Capitalism without complex systems of finance to lubricate investment and trade is unthinkable. Because money is highly mobile, most attention has focused on the international geography of money and the ways in which money supplies are regulated at the global scale.

The Bretton Woods agreements negotiated in New Hampshire following World War II, erected at the behest of the United States, led to the “Bretton Woods system” of international financial management and the General Agreement on Tariffs and Trade (GATT). Between 1947 and 1971, there was very little exchange rate fluctuation; most currencies outside of the Soviet bloc of states were pegged to the U.S. dollar, fluctuating only within 2% in a given year without International Money Fund (IMF) intervention. The dollar, in turn, was pegged to gold, at \$35 an ounce. The fixed exchange rate system required the free international movement of gold as well as minimal government interventions to offset its effects, such as changes in the money supply designed to change real interest rates. The regulations on

exchange rates imposed by Bretton Woods were largely designed to avoid the rounds of depreciations that deepened the Great Depression of the 1930s. Under this system of international regulation, currency appreciations or depreciations reflected government fiscal and monetary policies within a system of relatively nationally contained financial markets in which central bank intervention was effective. Trade balances and foreign exchange markets tended to be strongly connected: Rising imports caused a currency to decline in value as domestic buyers needed more foreign currency to finance purchases.

The system of stable currencies ended abruptly with the collapse of the Bretton Woods agreement in 1971 and the shift to floating exchange rates in 1973. The system’s demise reflected U.S. trade imbalances with its European partners and the overvaluation of the dollar, whose strength was maintained only through a steady outflow of gold. The accumulation of U.S. dollars overseas, which significantly enhanced the growing Euro-market in the 1960s, contributed to an increasingly unviable trade imbalance. Finally, President Richard Nixon announced that the United States would no longer abide by the Bretton Woods rules governing the dollar’s convertibility to gold, forcing a global switch to flexible exchange rates. Hereafter, supply and demand would dictate the value of a nation’s currency, and currency trading became big business.

The global sea change in capitalism that began with the traumatic petrocises of the 1970s, and the massive restructuring of industrialized economies (i.e., widespread deindustrialization), included a fundamental renegotiation of the relations between financial capital and space. Freed from many of the technological and political barriers to movement, capital has become not merely mobile but hypermobile. A key part of this new order was the emergence of what might be called stateless money, which originated in its contemporary form through the Euromarket. Originally, the Euromarket comprised only trade in assets denominated in U.S. dollars but not located in the United States; today it has spread far beyond Europe and includes all trade in financial assets outside the country of issue (e.g., Eurobonds, Eurocurrencies). One of the Euromarket’s prime advantages was its lack of national regulations:

Unfettered by national restrictions, it has been upheld by neo-classical economists as the model of market efficiency.

Capital markets worldwide were profoundly affected by the microelectronics revolution, which eliminated transaction and transmission costs for the movement of capital much in the same way that deregulation and the abolition of capital controls decreased regulatory barriers. Banks, insurance companies, and securities firms, which are generally very information intensive in nature, have been at the forefront of the construction of an extensive network of leased and private telecommunication networks, particularly fiber optics lines. Electronic funds transfer systems form the nervous system of the international financial economy, allowing banks to move capital around at a moment's notice, arbitraging interest-rate differentials, taking advantage of favorable exchange rates, and avoiding political unrest. Such networks give banks the ability to move money—by some estimates, more than \$3 trillion daily—around the globe at stupendous rates (the average currency trade takes less than 25 seconds): Subject to the process of digitization, information and capital become two sides of the same coin.

In the securities markets, global telecommunications systems facilitated the steady integration of national capital markets. Electronic trading frees stock analysts from the need for face-to-face interaction to gain information. The National Association of Securities Dealers Automated Quotation System (NASDAQ), the first fully automated electronic marketplace, is now the world's largest stock market, lacking a trading floor. Online trading allows small investors to trawl the Internet for

A collection of various currencies from countries spanning the globe. Money has been instrumental in the time-space compression of capitalism, the formation of the nation-state, and the rise of a global economy.

information, including real-time prices, eroding the advantage once held by specialists such as Reuters, and execute trades by pushing a few buttons.

The ascendancy of electronic money shifted the function of finance from investing to speculation, institutionalizing volatility in the process. Foreign

investments, for example, have increasingly shifted from foreign direct investment (FDI) to intangible portfolio investments such as stocks and bonds, a process that reflects the securitization of global finance. Unlike FDI, which generates predictable levels of employment, facilitates technology transfer, and alters the material landscape over the long run, financial investments tend to create few jobs and are invisible to all but a few agents, acting in the short run with unpredictable consequences. Furthermore, such funds are provided by nontraditional suppliers: a large and rapidly rising share of private capital flows worldwide is no longer intermediated by banks. Thus, not only has the volume of capital flows increased, but the composition and institutions involved have changed. Globalization and electronic money have had particularly important impacts on currency markets. Since the shift to floating exchange rates in 1971, trading in currencies has become a big business, driven by the need for foreign currency associated with rising levels of international trade, the abolition of exchange controls, and the growth of pension and mutual funds, insurance companies, and institutional investors.

The world of electronic money has changed not only the configuration and behavior of markets but also their relations to the nation-state. Classic interpretations of the nation-state rested heavily on a clear distinction between the domestic and international spheres, a world carved into mutually exclusive geographic jurisdictions. State control in this context implies control over territory. In contrast, the rise of electronic money has generated a fundamental asymmetry between the world's economic and political systems. Because finance has become so inextricably intertwined with electronic transfers of funds worldwide, it presents the global system of nation-states with unprecedented difficulties in attempting to reap the benefits of international finance while simultaneously attempting to avoid its risks.

MONMONIER, MARK (1943–)

A professor since 1969 and a prolific author, Mark Monmonier has made invaluable contributions to geography. Specializing in cartography, his work has been internationally acclaimed and is highly influential both inside and outside geography.

After obtaining degrees from Johns Hopkins University (BA, 1964) and the Pennsylvania State University (MS, 1967; PhD, 1969), Mark taught at both the University of Rhode Island and the State University of New York at Albany. In 1973, he accepted a position in the Department of Geography at Syracuse University, and after 25 years, he was awarded the prestigious title of Distinguished Professor.

Funded through institutions such as the National Science Foundation and the John Simon Guggenheim foundation, Monmonier's research has focused on a variety of cartographic topics. Demonstrated through his 200-plus articles and conference papers as well as 16 books, his breadth of knowledge and contribution to geography are extensive. His early interests focused on the use of computer algorithms in statistical mapping. In the late 1980s and through the 1990s, Monmonier became a leader in interactive or digital cartography, a subject matter now generally labeled GIScience. His 1982 book, *Computer-Assisted Cartography: Principles and Prospects*, is considered the first commercial textbook on computer cartography. Though his writings on computer algorithms, map design, and digital cartography were formative in GIScience, Monmonier's interests began to shift toward the social side of cartography, and by the 1990s, his research focused predominantly on 20th-century cartographic technologies and their societal impacts.

Monmonier's publications on social-mapping projects have helped advance understandings of the social, political, and historical contexts in which maps are made and used. More specifically, he has published critically acclaimed books on diverse topics such as journalistic cartography, election mapping, place names, and surveillance mapping. His insights on such topics have been formative in the critique of cartography as a social and political project—rather than a scientific or objective one. Published in 1996, *How to Lie With Maps* is perhaps Monmonier's most widely read and cited book. As useful as maps can be, he reminds his readers that they are generalizations and that they do "lie." Through his accessible writing and often humorous tone, he has taught academics, students, and the general public alike to maintain a cautious and skeptical perspective of maps. Indeed, in 2004, he was awarded a Globe Book Award for Public Understanding of Geography by the Association of American Geographers.

In addition to Monmonier's significant contributions in research and writing, he is an award-winning teacher and graduate advisor and has been an active member of several professional organizations. Some of Monmonier's notable service contributions include being the associate

editor and, later, editor of *The American Cartographer*, the president of the American Cartographic Association, and the editor for the highly regarded (and anticipated) sixth volume of the History of Cartography Project. As of 2009, Monmonier remains an active teacher and is deeply involved with numerous research and writing projects.

MONSOONS

The term *monsoon* derives from the Arabic word for season, *mausim*, and refers to the seasonal reversal in atmospheric circulation and the associated precipitation in tropical and subtropical regions. Such reversal of wind direction occurs with the seasonal migration of the Inter-Tropical Convergence Zone (ITCZ) in conjunction with the annual north-south progression of the sun. The movement of the ITCZ induces a temperature difference between the land surface and the ocean. The resultant difference in surface pressure between the ocean and land areas fuels the monsoon winds. This entry presents a brief review of how the monsoonal regions throughout the globe are demarcated and examines in detail the characteristics of the South Asian monsoon.

Monsoonal regions are presently identified by seasonal changes in cross-equatorial flows, changes in wet- and dry-spell transitions, and seasonal changes in divergent circulation in the upper troposphere associated with the large-scale atmospheric overturning taking place in tropical regions. Cross-equatorial flows occur when the mean wind flows across the equator along pressure gradients established due to land-ocean temperature contrasts. Monsoonal climates are characterized by distinct wet and dry spells with wet spells occurring during the monsoon season and dry spells at other times. The large-scale overturning of the atmosphere refers to the three-dimensional circulation associated with the monsoons. When the continental land masses heat up with the ITCZ overhead, large-scale convection or rising motion takes place. Such rising motion in the lower troposphere around 10° latitude is offset by subsidence around 20° . This results in divergent circulation in the upper troposphere. Simultaneously, meridional and zonal circulation cells are set into action with winds blowing in from the cooler surrounding oceans in response to the pressure gradient (see Figure 1).

Current methods emphasize that the monsoon is a global phenomenon where the different regional components interact with each other and the overall general circulation of the atmosphere.

The regional monsoonal components include the tropical and subtropical regions of Asia,

Australia, Africa, South America, and southwestern North America. These regions can be visually identified through the seasonal reversal in mean summer (July) and winter (January) winds at the 850-hPa (hectopascal) geopotential (potential energy of unit mass relative to sea level) height level (Figure 2). In South America, seasonal reversal of the winds is not as distinct as in other regions. The change appears in the direction of the cross-equatorial flow in the Amazon region. In North America, there is no cross-equatorial flow. However, there is a distinct seasonal reversal in mean winds.

Regional Monsoons

Asian Monsoon

The Asian monsoon is the most dominant regional component due to the influence of the Eurasian landmass, the Tibetan Plateau, and the Himalayan mountain range. W. Qian and colleagues demarcate four subcomponents: (1) the South Asian system over the Indian subcontinent and the Arabian Sea; (2) the Southeast Asian system, extending from the Bay of Bengal to Indochina and the southern South China Sea; (3) the East Asian system, extending over the northern South China Sea, eastern China, the Korean Peninsula, and Japan; and (4) the Tibetan Plateau system.

The Asian summer monsoon sets in when a heat low forms over the Eurasian landmass with the advent of the Northern Hemisphere spring. A land-to-sea surface circulation takes place in winter, when the oceans south of the Asian landmass warm with the southward migration of the ITCZ. The wintertime land-to-sea circulation is known as the Asian winter monsoon.

The summer monsoon of the South Asian subcomponent is the most well-defined and annually regular monsoon system due to the influence exerted by the Himalayas on the position of the subtropical jet stream. When the ITCZ lies over the Tibetan Plateau in the Northern Hemisphere spring, a heat low is established in the lower troposphere, while high pressure or divergence is established in the upper atmosphere. As a result, the subtropical jet stream switches north of the Himalayas and directs weather systems that draw

Figure 1 Schematic of the three-dimensional overturning circulation

moisture in from the surrounding cooler Arabian and Indian oceans toward land.

Australian Monsoon

The Australian summer monsoon sets in when the desert region of north central Australia heats up with the progression of the ITCZ south of the equator in the Southern Hemisphere spring. Northwestern Australia receives rainfall primarily in the form of thunderstorms when the heat low draws in moisture from the warm tropical oceans.

African Monsoon

The African monsoon prevails over the sub-Saharan and Sahelian regions of West Africa.

Moisture-laden air is transported from the eastern equatorial Atlantic in response to sensible heating over north central Africa during the Northern Hemisphere summer.

South American

A heat low is established over the Bolivian Andes when the ITCZ is south of the equator in the Southern Hemisphere spring. This draws in moisture-laden cross-equatorial winds from the Atlantic.

North American Monsoon

A heat low is established over the mountainous region in southwestern North America during the

Northern Hemisphere summer. This draws in moisture-laden southwesterly winds over northern Mexico and southwestern North America.

South Asian Monsoon

Impacts on Society

Rainy seasons in South Asia are associated with either the summer or the winter phase of the South Asian subcomponent of the Asian monsoon. The summer monsoon is the key rainy season in the Indian subcontinent. However, the winter monsoon is the major source of rainfall feeding the main agricultural season—the *Rabi*—in southern and southeastern India. It also feeds the main agricultural season—the *Maha*—in Sri Lanka. Rainfall over southern peninsular India and Sri Lanka is diminished during the summer monsoon and enhanced during the winter monsoon.

Extremes in the intensity of the summer and winter monsoons have been associated with devastating droughts and floods in the Indian subcontinental region. The impact of monsoonal extremes on society is profound, as agriculture is the mainstay of the economy in most countries in the region.

Understanding the mechanisms that govern the South Asian monsoon's onset, intensity, duration, and interannual variability is critical to assessing its predictability for purposes of agricultural decision making in the region.

Characteristics and Predictability

There appears to be a negative correlation between South Asian summer monsoon rainfall and the El Niño episodes (El Niño Southern Oscillation—ENSO), and vice versa during La Niña. However, while years of severe drought were associated with the failure of the summer monsoon during El Niño episodes, not all El Niño episodes have caused droughts over India. The exact reason for such fluctuations in the ENSO-monsoon relationship is as yet unclear. Theories have been put forth on the influence of Indian Ocean sea surface temperatures (SSTs) in modulating the ENSO-monsoon relationship.

The ENSO signal appears over the Indian Ocean in preferred interannual and decadal timescales. The signal is apparent in the influence of ENSO on the Indian Ocean dipole (IOD). The exact nature of the relationship between the IOD and the ENSO is as yet unclear. In fact, solar

cycles may modulate the connection between Pacific and Indian Ocean variability such that ENSO-related variability extends into the Indian Ocean during years of low solar activity, when weaker convective activity over the Indian Ocean makes it more susceptible to remote forcing and vice versa.

The South Asian monsoon is also closely related to a phenomenon called the Tropical Biennial Oscillation (TBO). According to the TBO theory, a strong monsoon in 1 year, accompanied by warm SSTs and intense convection, will cool the oceans, and the memory will carry on until the next year. The cooler SSTs will lead to a weaker monsoon and less cooling through latent heating, which will lead to a warmer atmospheric column and warmer SSTs that will in turn prevail until the next year. The amplitude of the TBO could be modulated during years of ENSO-IOD coupling, as the TBO is modulated by an 11-year solar cycle.

Land surface conditions over Eurasia are known to affect the strength of the summer monsoon such that higher than normal snow cover in the Tibetan Plateau and lower than normal snow cover in the Eurasian region precede heavy summer monsoon rainfall.

The South Asian monsoon has “active” and “break” cycles in a given monsoon season. These cycles have periods of 30 to 60 days. These active-break cycles are linked to intraseasonal oscillations (ISOs) associated with the northward propagation of convection. Studies have noted an inverse relationship between ISO activity and South Asian monsoon strength.

Anomalous convective heating over the equatorial Pacific during El Niño episodes results in westward-propagating Rossby waves. These Rossby waves are manifest as positive vorticity anomalies along the North African/Asian Jet. Cold air accompanies such positive vorticity anomalies and reduces the land surface temperature over Asia. This weakens the meridional temperature gradient, reduces the easterly vertical shear (difference of the zonal winds at 200 and 850 hPa over 50°E–90°E and 0°–15°N) of the mean zonal wind, and reduces the northward migration of the tropical convergence zone. This decreases the number of intraseasonal storms reaching land during a monsoon season and reduces the length of the

rainy season. The overall strength of the monsoon results from the interplay between ENSO, the TBO, ISOs, and the annual cycle.

Dynamical predictions of the Asian summer monsoon have not been successful. Current global circulation models cannot capture the ocean-atmosphere coupled variability and do not include land surface processes in an adequate manner. While statistical predictions of the monsoon have had far greater success than dynamical predictions, fluctuations in the quality of the statistical modeling of the monsoon highlight the need to understand the physical basis of the correlations.

Global Change and the South Asian Monsoon

Factors driving long-term trends in boundary conditions drive changes in the strength of the land-ocean temperature gradient and, thus, the strength of the monsoons. Such factors include Earth’s orbital changes, anthropogenic greenhouse gas concentrations, volcanic eruptions, and anthropogenic aerosol loadings. Surface wind speeds associated with the summer and winter phases of the East Asian monsoon declined significantly from 1969 to 2000 due to a weakening of the land-ocean temperature gradient, probably attributable to global warming. There is as yet no evidence on whether wind speeds associated with the South Asian summer and winter monsoons have declined. The Intergovernmental Panel on Climate Change’s Fourth Assessment Report projects an increase in the seasonal mean precipitation rate over South India, Sri Lanka, and the Indian Ocean immediately west of Sri Lanka during summer (June to August) and a decrease in the seasonal mean precipitation rate during winter (December to February) over southern India, the northern Bay of Bengal, and the seas adjoining eastern Sri Lanka in 2090 to 2099. Whether such an increase in summer precipitation and decrease in winter precipitation imply explicit changes in the strength of the South Asian monsoon is yet to be established.

MORRILL, RICHARD (1939–)

Richard Leland Morrill is best known as one of the quantitative revolutionaries who impelled geography toward more scientific epistemologies, theoretical sophistication, and quantitative modes of analysis during the mid 20th century.

He was born in Los Angeles in 1939. He received a BA in geography at Dartmouth College in 1955 and then pursued graduate work at the University of Washington, where he earned his doctorate in 1959. As a graduate student at

Washington, he was one of a small but influential group of students (including William Bunge, Brian Berry, Art Getis, and Duane Marble) under the tutelage of William Garrison, a doyen of the quantitative revolution in geography, who introduced his students to quantitative analysis. Walter Tobler was also a guiding figure for these “Space Cadets” at this time. Morrill taught briefly at Northwestern University in 1959–1960, undertook a postdoctoral research position at the University of Lund in Sweden in 1960–1961, and then returned to the University of Washington in 1961 to take up an assistant professorship. He remained at Washington for the rest of his career. Morrill officially retired in 1997, and he is currently Professor Emeritus.

Morrill’s interests have always been wide ranging and difficult to chart linearly, but his work exemplified two principles: (1) that geography should be a science, as science is the most valid and reliable means of getting at the truth (this stood in contrast with the largely descriptive and parochial aims of geography in the early part of the 20th century), and (2) that geographers should work toward social and spatial justice. (Morrill was a member of CORE [the Congress of Racial Equality] in the 1960s, was involved in the civil rights and other progressive causes, and in 1969 was one of the founding members of *Antipode: A Radical Journal of Geography*.) Systematically, his work has been categorized in terms of political, economic, health, urban, population, and transportation geographies. His research specialties have included social and economic inequality, political representation, redistricting and voting behavior, and modeling spatial behavior. His career has included longtime public service at various scales of government. For example, he has served on the U.S. Census advisory committee, the King County Boundary Review Board, and the Hanford Environmental Dose Reconstruction Project, as well as serving as an expert in various redistricting court cases in Washington, Mississippi, Indiana, and California. He served as president of the Association of American Geographers (AAG) and the Western Regional Science Association. His books include *Migration and the Growth of Urban Settlement* (1965), *Spatial Organization of Society* (1970), *Geography of Poverty in the United States* (1971), *Political*

Redistricting and Geographic Theory (1981), and *Spatial Diffusion* (1988), and he has written more than 200 journal articles. Morrill was also a recipient of a Guggenheim fellowship. To this day, he remains an avid hiker, especially in his beloved Cascade Mountains, east of Seattle.

MORSE, JEDEDIAH (1761–1826)

Father of Samuel Morse, inventor of the telegraph, Jedediah Morse (1761–1826) is sometimes called the father of American geography. After studying divinity at Yale, starting at age 14 and graduating in 1783, Morse became a prominent evangelical Calvinist preacher and man of letters in Charlestown, Massachusetts, near Boston, for 30 years. He was as involved in religious controversies as in geography: A staunch conservative, he wrote extensively in support of orthodox Calvinism and against the rising tide of liberal Unitarianism. In 1798, Morse famously warned of an Illuminati conspiracy, which earned him much ridicule. He was a strong Federalist and became disenchanted with the French Revolution. He was also a founder of the Andover Theological Seminary in 1808 and the American Bible Society in 1816.

As a teacher, he was dissatisfied with geography textbooks, all European in origin, which were inaccurate. During the years 1784 to 1804, Morse wrote numerous, highly popular geography textbooks. His most famous, immensely successful volume was titled *Geography Made Easy: A Short but Comprehensive System*, the first American geography text, first published in 1784 when Morse was just 23, which, with 23 editions, sold more than 400,000 copies by the 1830s. This bestseller about the emerging United States, which described Indians, New England Puritans, “uncultured Baptists,” and decadent slave holders, helped Americans understand their new country and formed an integral part of the project of

constructing nationhood and the new *geographical imaginaries* (i.e., symbolic, rather than physical, places, such as a nation or a diaspora) that it entailed. He followed this volume with *American Geography* in 1789.

Morse also published *The Elements of Geography: Adapted to the Capacities of Children and Youth, and Designed, From Its Cheapness for a Reading Book in Common Schools, as a Useful Winter Evening’s Entertainment for Young People in Private Families*, which first appeared in 1795 and went through four other editions, the last of which appeared in 1804. In 1789 and 1793 he published the two-volume *American Universal Geography*. In 1796, with the assistance of Noah Webster, he finished the first comprehensive geography of North America, titled *The American Gazetteer*, which included seven large foldout maps and 7,000 articles on various places, leaving a large legacy of colonial place names. His works helped greatly to popularize maps and cartographic literacy and made Morse the preeminent American geographer throughout the early 19th century.

His interests in geography included “civilizing” and Christianizing Native Americans. In 1820, he returned to Yale and accepted an appointment from the Secretary of War to do a major study of American Indians. He traveled for 2 years among Indian nations along the Canadian border and gained respect for their cultures; he attempted to rebut common racist stereotypes about them in an 1822 report.

MORTALITY RATE

The crude *mortality rate* refers to the incidence of death per 1,000 people among a given population and is thus essentially the same as the crude death rate; it is therefore closely linked to life expectancy. Mortality should not be confused with *morbidity*, the incidence or prevalence of a given disease. Demographers typically rely on age-specific and sex-specific mortality rates, which measure the number of deaths of a given 5-year age group of males or females. Mortality rates vary considerably across the life cycle, depending on the particular social circumstances in which people live. Typically, mortality rates tend to be relatively high for infants (especially in economically underdeveloped societies) and low during childhood and young adulthood, and then they rise steadily as a person enters middle age, increasing dramatically in old age. However, mortality is a complex phenomenon with multiple demographic, economic, sociological, psychological, cultural, and geographic dimensions.

Like fertility, mortality is a reflection of both biological circumstances (e.g., genetics, diet) and socio-environmental context. The causes of mortality vary greatly among societies (as well as within them). Infant mortality rates (number of deaths of babies less than 1 year old per 1,000 infants) are an important measure of a society's health, as infants are the most vulnerable members of any society. Typically, infant mortality rates are high in preindustrial societies, both historically and in the present; in much of sub-Saharan Africa, infant mortality rates exceed 120 per 1,000 babies. In contrast, economically developed regions such as North America, Japan, and Europe have infant mortality rates of less than 25 per 1,000.

In preindustrial social contexts, the leading causes of mortality are generally infectious bacterial (and to a lesser extent, viral) diseases, including, among others, respiratory infections (e.g., pneumonia), diarrheal diseases (e.g., dysentery), cholera, malaria, tuberculosis, and measles; today, that list also includes AIDS. Many of these diseases are waterborne. Thus, crude mortality rates in much of the developing world (Latin America, Africa, the Middle East, and Asia excluding Japan) tend to exceed 20 deaths per 1,000 people annually. As societies industrialize, the mechanization of agriculture and the correspondingly lower prices of food tend to improve diets and thus lower mortality rates and raise life expectancies. Improved public health measures (particularly, clean drinking water) and access to health care are also important. Thus, crude mortality rates in Europe, Japan, and North America are generally less than 7 deaths per 1,000 people annually. These changes are an integral part of the demographic transition that commonly accompanies industrialization.

Moreover, the decline in mortality rates is accompanied by a shift in the causes of mortality, a phenomenon often called the “epidemiological transition.” Essentially, mortality in economically advanced societies tends to result from environmental and behavioral causes, including obesity, smoking, and alcohol use, which produce proximate causes of death such as heart disease, strokes, and various forms of cancer. Excluding the middle aged and the elderly, other important causes include automobile accidents, homicide, suicide, overuse of prescription medications, illegal drug use, and household accidents.

MOST FAVORED NATION STATUS

The concept of most favored nation (MFN), referred to as normal trade relation (NTR) status since 1998, is a method of establishing reciprocal trading policies between countries. Within geography, the concept of MFN status has not been well applied. Within political and economic geography, leaders of countries have used this concept as a mechanism for enhancing their political position to secure and maintain their status in the global arena. However, historically, the term and the usage of MFN have their origins in the realist school of thought and, more recently, the liberal school.

The concept of MFN is found in two versions: unconditional and conditional. Unconditional MFN status is the highest level that a country can reach. Under this system, a trading partner is guaranteed treatment equal to that given to other favored trading partners without having to make a reciprocal concession. A conditional MFN trading partner gains treatment equal to that offered other favored trading partners, but only if it offers a concession in return. Under the General Agreement on Tariffs and Trade (GATT) and later the World Trade Organization (WTO), most countries today have some form of MFN status.

The earliest moments of the geopolitics of MFN in the United States are illustrated in The Articles of Confederation (1777), the Plan of the Treaties with France (1778), the Treaty of Amity and Commerce Between the United States and France (1778), the Treaty of Alliance Between the United States and France (1778), The Barbary Treaties (1786–1816), *The Federalist* (1787–1788), and the Treaty of Friendship, Limits, and Navigation between Spain and the United States (1795).

However, the 1930s ushered in a new movement within the geopolitics of MFN, which is illustrated in documents such as the speeches of Franklin Delano Roosevelt, the Reciprocal Trade Agreements Act (1934), and the League of Nations Economic Committee's Equality of Treatment in the Present State of International Commercial Relations: The Most-Favoured-Nation Clause (1936). Through these documents, there is a transition in how the United States used MFN status for setting and promoting its agenda

internationally. As of 2005, Cuba and North Korea were the only countries denied MFN status by the United States. However, current issues regarding the future of Iran's MFN status are being debated by members of Congress.

Although little work has been done within geography to analyze the relevance of MFN status, the issue is useful in analyzing countries' behavior regarding trade issues.

MOVIMENTO SEM TERRA

The Brazilian Movimento dos Trabalhadores Rurais Sem Terra (MST), or Landless Rural Workers Movement, is the most influential landless peasant movement in contemporary Latin America. The MST is a unique, family-based movement committed to the radical transformation of Brazil's unjust agrarian structure. Its current membership numbers more than 1.5 million people spread across 23 Brazilian states. The MST was established in 1984 in the city of Cascavel, in the southern state of Paraná, with the purpose of advancing land reform through the occupation of idle private and public lands. Since its inception, the MST has been led by João Pedro Stédile, a highly charismatic and effective peasant leader from the state of Rio Grande do Sul. Under his leadership, the MST has spearheaded a slow but firm process of land reform in Brazil. Its success

has inspired the creation of similar movements in other Latin American countries. The MST has also played a key role in the global struggle for land reform by actively participating in the Via Campesina, an international peasants' movement that seeks to build solidarity among farmers' movements around the world

The Socioeconomic Context

The history of the MST is intrinsically linked to the history of land dispossession in Brazil since colonial times. The root causes of this dispossession can be traced to the *latifúndia* system (a semifeudal organization of large estates) established by the Portuguese crown during the 16th century to secure both territorial control and economic benefits. Initially, these large estates were granted to selected *donatários* (influential Portuguese noblemen) for their services and loyalty to the crown. The *donatários* developed and administered these large estates on behalf of the Portuguese crown. They also "pacified" indigenous peoples resistant to Portuguese rule by "incorporating" them into the colonial society and economy. Eventually, the crown granted the *donatários*, or their descendants, legal ownership of these large estates. These early *latifundiários*

(large estate landowners) laid the foundation for the establishment of a privileged and powerful landholding class that continues to play a preeminent role in Brazil's social, political, and economic life.

In contrast to the progressive land-granting traditions of the United States, Canada, and Australia, land granting in Brazil was designed to benefit a small minority. Indeed, the establishment, and eventual expansion, of the *latifúndia* system led to an enormous concentration of land in the hands of a few, leading to the uprooting and impoverishment of peasants and the degradation of forest resources, particularly in the Brazilian Amazon. These problems intensified in the 1960s and subsequent decades with the introduction of agricultural modernization. Globalization has further exacerbated this situation. Currently, almost 46% of the country's total registered agricultural land belongs to 1.6% of landowners (Table 1), and more than 20 million rural people live in poverty, including 5 million landless peasants. Notably, most of the agricultural land is presently under corporate control (Table 2).

The unjust agrarian structure has given rise to intermittent peasant rebellions. For example, in the early 1960s, under the leadership of the Peasant Leagues, landless peasants mobilized across Brazil to demand comprehensive land

Rural Property Size (hectares)	Number of Properties	Percentage of Properties	Area (hectares)	Percentage of Area

reform from the “leftist” government of João Goulart (1961–1964). In response, frightened *latifundiários* called for military intervention and greeted with relief the military coup of 1964. The military acted swiftly and roughly to reassert control, banning peasant organizations and brutally repressing the peasant leaders. This repression effectively quelled peasant activism until the mid 1970s.

In 1976, the military decreed the expropriation of large tracts of peasant lands to construct the gigantic Itaipú dam along the border with Paraguay. Although the military promised fair compensation, the country’s economic crisis delayed compensation, thus angering the peasants. In response, peasants began to occupy idle public land in the area around Itaipú, with the endorsement of the Catholic and Lutheran churches. The success of these land occupations triggered a wave of similar occupations by landless peasants across southern Brazil in the late 1970s. Over the following years, landless peasants mobilized across Brazil, again with the support of the Catholic Church. In 1984, many of these landless peasant groups came together in Cascavel and established the MST as a national landless peasant organization, with the goal of

pursuing comprehensive land reform. The MST adopted political autonomy and collective leadership as two fundamental organizational principles. It also encouraged the active participation of the whole family in the movement.

The MST’s Praxis

The MST employs both political and economic activism to promote its objectives. This integrated approach teaches the landless to holistically advance sustainable rural livelihoods. Over the past two decades, the MST has achieved remarkable results. First, it has compelled the Brazilian government to redistribute more than 12.5 million hectares of land. Second, the MST has obtained land titles for more than 500,000 landless peasants linked to the movement. Third, it has established hundreds of agricultural settlements, several alternative media outlets, an extensive welfare system, and dozens of agricultural cooperatives and food-processing plants. This is a considerable achievement given the MST’s limited material resources (Table 3).

The MST has encountered serious difficulties in confronting the *latifúndia* system. First, the

<i>Military and Democratic Regimes (Period)</i>	<i>No. of Peasant Families Settled¹</i>	<i>Set Target</i>	<i>Total Area (million hectares, approximate)</i>	<i>Average per Year</i>
Military (1964–1984)	77,465	N/A	13.8	3,873
Sarney (1985–1989)	89,950	1,400,000	4.5	22,487
Collor and Franco (1990–1994)	60,188	N/A	2.3	15,049

Notes:

1. Most of these families received land titles via colonization and settlement projects. Although during the 1995–2002 period there was a substantial increase in the granting of land titles, the total number fell short of the 1.4 million target set in 1985.
2. Cardoso’s figures have been hotly contested. In 2006, INCRA revised its figures for 1995–2002. As a result, the total number of beneficiaries decreased from 628,141 to 592,141.
3. During the first term of his mandate, Lula settled peasant families mostly on public land.

pursuit of sustainable rural livelihoods through cooperativism has often been conflict ridden and sometimes divisive. Second, the MST has had limited political support in urban centers. Third, under pressure from the powerful *latifundiários*, the Brazilian government has been unwilling to implement comprehensive land reform and to properly fund postsettlement programs. Finally, the growing interest in biofuel has reenergized the *latifúndia* system. Successive Brazilian governments have encouraged the opening of new agricultural frontiers, such as those in the state of Mato Grosso, by providing financial, technical, and marketing resources. The new prominence of the *latifúndia* has seriously undermined land reform efforts. Newly settled peasants are confronting their lack of access to educational, financial, technological, and marketing resources. The MST has challenged the government to assume its responsibility in providing these resources.

Despite the above constraints, the MST is determined to continue its struggle for land reform and has expanded its grassroots political support in urban centers. It has also reached out to environmentalists, human rights groups, labor unions, and other social actors. It has become a powerful voice for the rural poor and disenfranchised. Embracing political and economic activism to vigorously contest centuries of systemic socioeconomic exclusion, the MST's community-based approach to land reform offers great potential for effectively advancing sustainable rural livelihoods in Brazil.

MULTIMEDIA MAPPING

Multimedia mapping refers to the integration of computer-assisted mapping systems and multimedia technologies that allow the incorporation of both spatial geographic (i.e., geospatial) information in digital map format and multimedia information. The term *multimedia* implies the use of a personal computer (PC) or the Internet with information presented through the following media: (1) text (descriptive text, narrative, and labels), (2) graphics (drawings, diagrams, charts, snapshots, or photographs), (3) digital video (television-style material in digital format), (4) digital audio sound (music and oral narration), and (5) computer animation (changing maps, objects, and images). Multimedia technology has been extensively used by commercial encyclopedia CD-ROMs, such as Microsoft Encarta Encyclopedia CD-ROM, to provide a multisensory learning environment and the opportunity to improve the understanding of a concept.

Multimedia mapping has gone through several stages. The first stage was the development of interactive maps and electronic atlases during the 1980s. The interactive map is a computer-assisted form of map presentation and is characterized by an intuitive graphical user interface that allows the

user to manipulate the map features through a computer mouse. The link to multimedia information is achieved through superimposing “hotspots” on the cartographic features of the map or on scanned aerial photographs. Interactivity becomes a key feature of the interactive maps, which allow the user to explore more detailed information in the area predefined by the map developer. Examples of early electronic atlases include the BBC’s Domesday Project and Goode’s World Atlas.

The second stage was the development of the hypermap in the early 1990s. Coined by Laurini and Milleret-Raffort (1990), the term *hypermap* describes a multimedia hypertext document with geographical access. In other words, the hypermap is an interactive, digital multimedia map that allows users to zoom and find locations using a hyperlinked gazetteer. The underlying principle of the hypermap is the concept of hypertext. Hypertext represents a single concept or idea. By activating predefined hyperlinks, it is possible for the user to connect a hypertext to other nonlinear text information. If the hypertext is linked to multimedia information, the term *multimedia hypertext* or *hypermedia* is used. Therefore, the hypermap is also called cartographic application of hypertext or hypermedia mapping. The development of hypermaps was made possible with Apple’s Hypercard software, developed for the Macintosh computer and released in 1987. Examples of hypermaps include the Glasgow Online digital atlas and Hypersnige.

The third stage involves the integration of a hypermedia system (which features hypertext, hyperlinks, and multimedia) and a geographic information system (GIS), namely, hypermedia GIS. GIS is a digital mapping and analytical tool that is used to capture, retrieve, manipulate, and display geographic information and features linking of cartographic features with their alphanumeric attributes to perform spatial analysis. Recently, there has been increasing interest in integrating multimedia information in GIS. Shunfu Hu (1999) developed an approach for integrating multimedia data with a GIS database for an area in Everglades National Park. The multimedia database contains descriptive text, ground photographs, digital video clips, and audio segments highlighting the characteristics of Everglades plant communities, individual species, and invasive

exotics, as well as plant-animal interactions, hurricane damage, and postfire vegetation succession. It is linked to a GIS database that includes detailed vegetation maps, satellite imagery, and scanned aerial photographs. The integrated multimedia approach system was implemented in two steps: (1) an interactive multimedia system designed to manipulate multimedia information such as hypertext, hyperlinks, scanned photographs, digital video, and sound was developed in a Microsoft Visual Basic programming environment and (2) a GIS application program to manipulate spatial data was constructed using Visual Basic and Environmental Systems Research Institute (ESRI) MapObjects software. The hypermedia GIS approach provides a unique way to represent geospatial features and associated information on interrelationships between flora, fauna, and human activities in Everglades National Park.

The latest development in multimedia mapping is the convergence of digital mapping, multimedia content, and a global positioning system (GPS). Commercially available hardware such as Red Hen Systems provides photo and video mapping hardware for field data collectors to collect georeferenced digital video imagery with a GPS. Red Hen Systems also provides multimedia mapping software such as MediaMapper and GeoVideo for ESRI ArcGIS to process the video imagery and generate multimedia maps. This type of integrated multimedia mapping system provides an intuitive connection between locations (where) of interest and what they look like.

Multimedia mapping is the direct result of advancement of computer technology, mapping techniques, and GPS, all of which are combined together to allow the collection, exploration, and visualization of geospatial information in digital map format and associated multimedia content (e.g., text, photographs, sound, and video). An obvious advantage of multimedia mapping is the ability to incorporate the multimedia content in a digital map environment that brings vital information to the user.

to develop true-color photographs, again, in the visible spectral zone, where human eyes perceive reflected sunlight radiation. Multispectral imaging systems simultaneously obtain a series of images recorded at a number of different spectral zones, far beyond the visible light. Multispectral imaging is used in many areas of science and technology but is most widely developed in astronomy, especially in radio astronomy, and in Earth remote sensing, in particular for Land Use and Land Cover Mapping. Images taken at different wavelengths can be combined to make composite images by displaying the image for each wavelength as red, green, or blue in the final image. These composite images result in color patterns that can be used to identify surface features.

Multispectral imaging is based on principles of spectral radiometry. Radiometry is the measurement of optical radiation, which is electromagnetic radiation within the frequency range between $3 \times 1,011$ Hz (hertz) and $3 \times 1,016$ Hz. This range corresponds to wavelengths between 0.01 and 1,000 μm (micrometers) and includes the regions commonly called the ultraviolet, the visible, and the infrared. A radiometer is a device used to measure the power in electromagnetic radiation. Radiometers can use different types of detectors, for example, thermal detectors or photon detectors (photodiodes). Once the detector absorbs the energy, it quantifies it and converts it into an analog signal or, in modern radiometers, into a digital number. The analog signal can be registered in a film and produce a picture, where the image density corresponds to the amount of energy, registered by a radiometer. Modern multispectral systems use digital imaging technologies, where each multispectral image consists of a two-dimensional array of picture elements (pixels) and the brightness of each pixel corresponds to the amount of registered energy for the corresponding surface element. Such multispectral images can be thought of as a multilayer data set, where each layer corresponds to a particular zone of the electromagnetic spectrum.

Multispectral imagery is widely used in remote sensing for automated image classification, which is based on differences in spectral reflectance of an object in different parts of the electromagnetic spectrum, called a spectral signature (or spectral curve). There are a fair number of different

MULTISPECTRAL IMAGERY

General principles of imaging are based on the registration of electromagnetic energy in particular zones of the electromagnetic spectrum using a particular sensor. In classical photography, reflected sunlight is registered in light-sensitive film. The first photographic films were sensitive in the visible spectral zone and had only one layer to record the integral amount of acquired energy; the films (and produced photographic prints) were black-and-white. The later films were composed of three layers, sensitive to three primary colors—red, green, and blue—which allowed us

Because different materials reflect and emit energy in different ways, the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), with its multispectral infrared channels, can provide detailed information about the composition of Earth's surface. In this three-dimensional perspective view looking north over Death Valley, California, ASTER's bands 13 ($10.6\ \mu\text{m}$), 12 ($9.1\ \mu\text{m}$), and 10 ($8.3\ \mu\text{m}$) are displayed in red, green, and blue, respectively. Salt deposits on the floor of Death Valley appear in shades of yellow, green, purple, and pink, indicating the presence of carbonate, sulfate, and chloride minerals.

techniques used to extract qualitative and quantitative information about the surface from the recorded images, using analysis of the extracted spectral signatures. Spectral differences in reflectivity at certain wavelengths, identified for the same object in different layers of a multispectral image, can be used to detect and separate objects on Earth's surface. In many cases, the spectral signature of an object can be registered by laboratory or field spectrometry, where a continuous reflectance spectrum of the sample is measured through a defined wavelength region. If such a spectral signature is known for a particular object, similar objects can be delineated, classified, and identified based on matching a discrete spectral pattern, extracted from bands of a multispectral image, against the known spectral curve of the sample object. Laboratory-based measurements of spectral signatures of many materials and objects on Earth are collected by different institutions and are available as spectral databases (spectral libraries, such as ASTER spectral library, maintained by NASA's Jet Propulsion Laboratory, or USGS digital spectral library).

The first film-based multispectral imaging systems comprised four to six synchronized cameras with optical filters transparent to certain wavelengths. The images had classical frame geometry and were composed of optical projectors to produce color composites. Modern digital multispectral systems are usually based on charge coupled device (CCD) arrays and fall into two categories: (1) frame sensors, which use square or rectangular CCD arrays and have geometric characteristics similar to a film camera, and (2) line sensors (scanners), which use linear CCD arrays and therefore have noncentral projection geometries. Multispectral data acquired by such systems range from 0.40 to $2.50\ \mu\text{m}$ and typically consist of 4 to 7 bands of data with single bandwidths 0.07 to $0.20\ \mu\text{m}$ wide. Advanced sensors, acquiring 200 or more bands of data,

are called hyperspectral systems and have a single bandwidth as narrow as $0.01\ \mu\text{m}$.

Multispectral imaging systems can be installed onboard an airborne platform. The first experiments on the use of spectral aerial photography for classification of vegetation were performed in the 1950s. In the 1960s, NASA initiated a large number of studies of different applications of color infrared and multispectral photography.

The first orbital multispectral photograph was acquired by Apollo 9 in 1969 to assess the applicability of such imagery for observation of Earth resources. The first Earth Resources Technology Satellite (ERTS-1), specifically designed for global collection of multispectral images for Earth remote sensing, was launched in 1972. ERTS-1, later renamed in Landsat-1, was followed by the series of Landsat satellites, of which the latest, Landsat-7, is currently in orbit. Landsat 7 was launched in April, 1999, and placed at an altitude of 705 km (kilometers). Landsat 7 employs the Enhanced Thematic Mapper Plus (ETM+) sensor, which continuously collects digital multispectral data in

This May 19, 2000, subscene of the U.S.-Mexico border in California covers an area of 24×30 km. The combination of visible and near-infrared bands displays vegetation in red. The border town of Mexicali-Calexico spans the border in the middle of the image; El Centro, California, is in the upper left. The dramatic difference in land use patterns between the United States and Mexico is highlighted by the lush, regularly gridded agricultural fields of the United States and the more barren fields of Mexico. The Imperial Valley of California is one of the major fruit and vegetable producers for the United States, watered by canals fed from the Colorado River.

Source: NASA/GSFC/METI/ERSDAC/JAROS and U.S./Japan ASTER Science Team.

seven spectral bands from 0.45 to 2.35 μm , and one panchromatic image with 0.52- to 0.90- μm wavelengths. The sensor swath width is 185 km, and spatial resolution on Earth's surface is 30 m (meters) for all spectral bands, apart from 60 m for infrared and 15 m for panchromatic bands.

Since the beginning of the era of satellite remote sensing, a large number of visible and infrared imaging sensors have been flown into space to study Earth and other planetary surfaces. These include Landsat (USA), ALI (USA), SPOT (France), IRS (India), JERS (Japan), ASTER (Japan-USA), CBERS (China-Brazil), PRIRODA (Russia), and many others.

MULTISTAKEHOLDER PARTICIPATION

In contemporary development processes in cities and regions, stakeholder participation among vested-interest groups is often a core activity and seen as more or less mainstream. Such development processes may be of different kinds, for example, addressing spatial planning, neighborhood regeneration, environmental improvements, or behavioral change. The stakeholders involved may also belong to very different categories, for example, the general public, those most affected by these decisions in their daily life, or those with a financial interest in the development. However,

multistakeholder participation in decision analysis tends to become quite complex, and the outcomes can be both positive and negative. To navigate among these pros and cons, it becomes necessary to carefully shape any approach to multistakeholder participation according to the specific conditions of each development process. To successfully facilitate such a customization, it is essential to carefully respond to four guiding questions regarding the participation: Why? Who? When? and How?

Why Participate?

A key entry point, and possibly the most critical question, in each individual participatory process is to clearly resolve the question of *why* extended participation would be required. There are several potential benefits of stakeholder participation, since it may achieve the following:

- To different degrees, delegate influence (and responsibilities) to involved parties
- Ensure the longevity of measures, for example, by developing and securing effective and continuous management of built or social structures
- Resolve differences or placate upset stakeholders when different values and perspectives openly enter into the negotiation
- Build good working relationships among stakeholders
- Get more, and more diversified, knowledge into a planning process, also including diverging values, and thus improve the quality of both the process and its result when issues are assessed from a variety of viewpoints
- Increase stakeholder support, which may include both financial and political backing
- Strengthen trust in involved institutions
- Inform and educate those affected, or the public in general, about the intentions and content of a development project
- Ease implementation of the proposed project

From an ethical perspective, the above list can be seen as ranging between more destructive aims, such as manipulation and therapy in the worst case, up through more positive processes of collaborative knowledge production, social

learning, and negotiation and then toward increased emancipation and shared power among stakeholders.

Moreover, a high degree of caution is needed to evade the wide range of potentially negative outcomes of stakeholder participation. Those with the most power may manipulate the process to favor their own interests and those of actors with no real “stake” in the matter and thus abuse the process for political purposes to the disadvantage of genuine stakeholders. Public officials and/or politicians may refuse to accept results from the process, arguing that they themselves represent the public interest and safeguard the common good. In such processes, there are often delays, since the involvement of diverse stakeholders leads to more feedback loops and thus less streamlined procedures. Costs increase, for example, for the process facilitator, the participating staff, communication materials, and meetings; and new professional skills are needed for facilitating processes, conflict resolution, and communication.

Although it is clear that it may be possible to have many different, and sometimes conflicting, aims when promoting participation, these intentions are seldom clearly stated. Instead, the “why” question is often only implicitly addressed by those initiating such processes. It tends to drown in general and quite unclear assumptions that participation is a “good thing” in itself. This is a problem, since the various approaches and methods to support stakeholder interaction are likely to support very different outputs. If a development process seeks social learning, it will probably need a process design that is distinct from what is required for information purposes, not to mention truly decentralized decision making. Vagueness regarding the purpose of stakeholder participation may thus seriously undermine the foundation of any participative process.

Who Participates?

After the “why” question has been answered, the process initiator—for example, a local or regional government—should have clearly formulated objectives for any extended participation in a particular process. Based on these objectives, it then becomes possible to start exploring *who* should participate, in order to satisfy them.

In a broad sense, a stakeholder is anyone who declares himself or herself to have a stake in an issue—assuming that if someone claims to have a stake he or she probably is affected by the proposed development in one way or another. From such a perspective, most development processes are participatory, insofar as they seldom are the accomplishment of one single person. But what is most important here is the participation of those stakeholders not normally involved. As an example, in the case of spatial planning, this would refer to participation of individuals outside of the municipality’s own planning department and board. Such external stakeholders could be members of the public or local inhabitants, also officials from other municipal departments, external experts, representatives from business, or even researchers.

In some development processes, it may be a good strategy to invite anyone to participate, for example, in the initial phases of larger urban renewal initiatives, where the objective may be to raise general awareness of future activities or to scan public opinion. In other processes, it is probably a good idea to delimit the scope of participation based on particular objectives. In endeavors where specific knowledge is critical, for example, concerning the socioeconomic effects of a certain urban regeneration program, experts of different kinds might be invited to participate. Such experts can be professionals, such as sociologists or economists, and also “local experts” with deep knowledge of the local conditions. When an issue is politically sensitive and the objective is to unlock conflicts and facilitate negotiations and agreement, it becomes essential to ensure that all conflicting views are represented among the participants. If the implementation of a project largely depends on the active participation of local inhabitants, local communities are the primary centers of attention.

To get this right, objectives need to be linked to a mapping of potential stakeholders and their different characteristics. Depending on the nature of the objectives, such a mapping may focus on different qualities, such as the following:

- Those being affected in different ways, distinguishing between those most directly affected and those just having an interest

- Key organizations in different societal sectors, such as citizen groups, communities, nongovernmental organizations, municipalities, business, and local, national, and regional governments
- Key individuals in such organizations, who may “own” a problem or the potential solution to that problem
- Geography, for example, in terms of people living near a certain location or downstream of an intervention
- People who may contribute with different kinds of resources
- The various parties to potential conflicts

Finally, to be able to analyze, understand, and communicate the results of any stakeholder mapping, it is helpful to make use of different graphical representations.

When Should Participation Occur?

On many occasions, wider stakeholder participation is fully justified. The quality of plans and decisions will improve, the long-term sustainability of interventions will be strengthened, and matching between the judgments of officials and experts, on the one hand, and the considerations of different stakeholder groups, on the other, will be better secured. Even so, stakeholder participation often consumes time, effort, and money and also demands trust and endurance among stakeholders. It is easy to wear out both stakeholders in general and those trying to facilitate the participation.

Consequently, it is necessary to be meticulous when determining, first of all, *if* and, then, *when* moments of wider participation should be initiated. There is no place for general calls for participation; instead, quite strategic judgments must be made of “who is good for what and when.” Here, it is extremely helpful to develop some kind of participation timeline, where (a) different objectives are linked to the participation of certain stakeholders, (b) these moments of participation are positioned along the timeline, and (c) estimated costs (in time, effort, money, trust, and endurance) may be added to each moment.

Accordingly, one single development process may consist of several participative subprocesses,

with different sets of stakeholders taking part and pursuing different objectives. From the timeline, it becomes possible to better understand how long each one of these subprocesses should take, how many and which stakeholders need to be involved, and what costs are included. Ultimately, this makes it possible to judge whether participation is critically necessary, just desirable, or at all feasible in relation to the established objectives.

How Should Participation Take Place?

As discussed above, participative processes should be carefully tailored to the intended purpose(s). The next step is to determine how the objectives of participation may be supported by different methods and tools for setting up and facilitating multistakeholder participation—taking the mapping of potential participants, the available timeframe, and the existing resources (once again including time, effort, money, trust, and endurance) into account.

Fortunately, there are a large number of participative methods, each one with its strengths and weaknesses. However, it may become quite difficult to navigate amid this plethora of potential approaches. Some of the approaches are quite extensive and all-inclusive, while others have been developed by consultants or researchers for particular situations or applications. For the individual professional, it is important to develop a framework for assessing the strengths and weaknesses of different approaches. Such a framework would support the understanding of how best to approach participation within a particular development process. Also, since development processes often address complex and composite problems, it is often beneficial to combine different methods to be able to best address a set of objectives, mix of participants, timeframes, and available resources.

Finally, a critical aspect for a successful participative process is how well power relations among participants are handled. Even if there is agreement on overall development objectives, participants will ultimately strive to promote their own (or their group’s) short-term and/or long-term goals. This is not altogether negative but should be expected and confronted. However, an even more critical success factor is the management of

the power relationships that always exist between the group of participants and a variety of external stakeholders. These may be government officials active in mainstream planning or decision making, stakeholders partaking in parallel development processes, or actors in different organizations with some authority over the overall setting of the development process. If these external power relationships are not handled properly, long-term progress is seldom accomplished.

MULTITEMPORAL IMAGING

Multitemporal imaging is the acquisition of remotely sensed data from more than one time period. Acquiring multiple views of natural or built features through time provides an enhanced

ability to accurately identify these features, significant information about how our world is changing, and unique insight into the relationships between the environment and the impact of human activities. Multitemporal images and analysis techniques provide the tools to monitor land use and land cover change (LUCC) and have been instrumental in providing an understanding of global environmental change. Our understanding of the impacts of global change would not have been possible without multitemporal imaging of diverse phenomena such as snow and ice extent, sea surface temperature, deforestation, drought, water resources, wildfire, desertification, and more.

Imaging Systems for Multitemporal Studies

Multitemporal imaging began with the earliest applications of aerial photography, in which government agencies in the United States regularly acquired aerial photos to monitor agricultural production and soils. These photographs are available from the 1930s onward and are still being used in studies of long-term landscape change. A wide range of Earth-observing satellite systems are now available for multitemporal studies. These systems have varying spatial (size of the smallest resolvable feature), spectral (wavelengths sensed), and temporal (repeat cycle of image acquisition) resolutions. The goal of any multitemporal study will dictate the best combination of spatial, spectral, and temporal resolutions to use.

Moderate-spatial-resolution (~20- to 30-m [meter] pixel size) satellites such as Landsat (first launched in 1972) generally provide repeat coverage of the same spot every 2 to 3 weeks. We therefore have more than 35 years of data from the Landsat satellites for multitemporal studies. Data from Landsat and subsequently launched moderate-spatial-resolution systems such as France's SPOT (Satellite Pour l'Observation de la Terre, first launched in 1986) and the Indian Remote Sensing (IRS) satellite (first launched in 1988) provide multitemporal data across the globe.

Satellite systems that can provide daily coverage of every spot on Earth have a relatively coarse spatial resolution (~1-kilometer pixel size).

Nevertheless, these systems have been ideal for global monitoring of the atmosphere, vegetation, glacial extent, sea surface temperature, and other more ephemeral phenomena. The National Oceanic and Atmospheric Administration's (NOAA) Advanced Very High Resolution Radiometer (AVHRR) began collecting data in 1979, and subsequent AVHRR sensors have provided continuous daily coverage of the Earth. France's SPOT VEGETATION system, first launched in 1998, also provides daily coverage for multitemporal studies of vegetation condition. The United States first launched a more advanced version of the AVHRR system in 2000, called the Moderate Resolution Imaging Spectrometer (MODIS). MODIS was specifically designed to provide long-term multitemporal data to improve our knowledge of global dynamics. Acquiring spectral data in the visible, near-infrared, and thermal-infrared regions of the electromagnetic spectrum, MODIS provides daily data to study the atmosphere, ocean, and land surface at spatial resolutions of 250 to 1,000 m.

More recently, commercial satellite systems have become available that provide very high-spatial-resolution data (0.6–3 m) on an on-demand basis. High-resolution data from these systems can be reacquired in 1- to 5-day time periods, and their high spatial resolution can be an invaluable asset in disaster management and urban planning.

Digital Analysis Techniques for Multitemporal Studies

To make effective use of multitemporal image data requires more rigorous initial digital processing. This preprocessing is required to ensure that images acquired from different sensors through time are (a) radiometrically calibrated to correct for sensor variation, (b) corrected for variation in atmospheric conditions, and (c) geometrically registered to a map base so that pixels from different dates overlay spatially. Without these corrections, it would be impossible to quantitatively compare reflectance values from one image date to another.

Selection of images to use in multitemporal studies also requires consideration based on the specific objectives of the study. It is important for

researchers to take into account naturally occurring changes that may affect their ability to monitor the specific change they are interested in. Time of year, rainfall, temperature, soil moisture, and vegetation growth cycle all must be considered in selecting the images to be used. Studies designed to monitor specific phenomena from one year to the next generally seek to use data from as close as possible to the same day or month.

A wide range of digital processing techniques for multitemporal image analysis have been developed and employed. The most widely used technique involves the classification of each date in the analysis. The classes chosen reflect the nature of the change to be identified; through post-classification comparison, this technique has the advantage of providing specific from-and-to change information. However, this technique is quite sensitive to the accuracy of the individual classifications. Multidate images can also be combined into a single classification whose output reflects both land cover/use classes that have remained the same and classes that have changed. Multitemporal principal components analysis (PCA) can be successfully applied to both multidate and long-time-series data to extract information on change. When multidate image data have been properly preprocessed, it is possible to directly compare values in a single band or a vegetation index from date to date using an algebraic function (e.g., subtracting one date from another). More advanced multitemporal analysis techniques include spectral change vector analysis and the use of artificial neural networks.

Applications

The range and depth of applications using multitemporal imaging spans geography and multiple sciences. These applications encompass both physical and human geography. Physical studies often focus on biophysical, ecological, and environmental change and use multitemporal images to monitor vegetation change, deforestation, agricultural production, rangeland health, soil moisture, snow and ice, flood dynamics, lake and ocean water quality, invasive species, drought, and desertification. Human-geography-related applications include urban planning and growth monitoring, urban hydrology, population

dynamics, fire detection and management, transportation planning, socioeconomic and quality-of-life analyses, disaster emergency response, and monitoring the impacts of human activity on the environment.

MULTIVARIATE ANALYSIS METHODS

Multivariate analysis methods are defined as statistical procedures that involve the analysis of more than one variable at a time, with an emphasis on modeling the relationships between such variables. The use of these methods in geography became a significant component of the “quantitative revolution” within the discipline during the 1950s and 1960s and has been further stimulated by the widespread use of GIScience and a renewed interest in spatial

statistics from the 1990s. Multivariate analysis methods are broadly classified into two categories: dependence and interdependence techniques. A dependence technique is one where a single variable or a set of variables is identified as the dependent variable to be explained or predicted by other variables known as explanatory or independent variables. An interdependence technique involves the simultaneous analysis of all variables in the data set; variables are not classified as dependent or independent.

Multivariate dependence techniques can be classified as those analyzing a single dependent variable (e.g., multiple regression, discriminant analysis, logistic regression), more than one dependent variable (e.g., analysis of variance), and several dependent-independent relationships (e.g., canonical correlation). *Multiple regression analysis* is used when a single dependent variable is assumed to be statistically associated with at least two independent variables. The goal is to predict changes in the dependent variable in response to changes in values of the independent variables. The statistical rule of least squares is frequently used to achieve this goal. If the dependent variable is qualitative or categorical, *multiple discriminant analysis* is the appropriate multivariate technique. Discriminant analysis is used when a sample can be classified into groups based on a dependent variable that comprises several known categories. The goal is to explain group differences and predict the likelihood that an observation belongs to a particular group, based on a set of quantitative independent variables. *Logistic regression* modeling, or logit analysis, combines multiple regression with discriminant analysis—a set of independent variables are used to predict a categorical and usually dichotomous dependent variable. The key difference between logistic regression and discriminant analysis is that the former includes both qualitative and quantitative independent variables and is not subject to assumptions of normality. *Canonical correlation* analysis is a logical extension of multiple regression with several quantitative dependent variables. The objective is to develop a linear combination of both sets of variables (dependent and independent) such that the correlation between the two sets is minimized. *Multivariate analysis of variance* (MANOVA) is an

extension of the more common univariate analysis of variance (ANOVA), which is used to simultaneously investigate the relationship between several qualitative independent variables (treatments) and at least two quantitative dependent variables. MANOVA is frequently applied in experimental design situations that involve the manipulation of several treatment variables to test hypotheses regarding variation in group responses across multiple dependent variables. *Multivariate analysis of covariance* (MANCOVA) is sometimes combined with MANOVA to remove the effect of uncontrolled quantitative independent variables on the dependent variables, after the experiment.

In multivariate interdependence techniques, all variables are analyzed simultaneously to find an underlying structure that is applicable to the entire set of variables. The choice of the specific technique to be used depends on whether (a) the structure of variables is to be analyzed (factor analysis), (b) observations are to be classified to represent structure (cluster analysis), or (c) our interest is in understanding the structure of observations (multidimensional scaling). *Factor analysis* is essentially a data reduction technique used to investigate interrelationships among a large number of variables and to explain these variables in terms of their common underlying dimensions (factors). The goal is to find a way to reduce the information contained in the large set of original variables into a smaller subset with minimal loss of information. Factor analysis provides empirical estimates of the structure of variables considered and thus serves as an important basis for creating summated scales. *Cluster analysis* is a technique for classifying individuals or objectives into a smaller number of mutually exclusive and relatively homogeneous subgroups. This technique typically involves at least three steps: (1) measurement of the association among observations to determine the number of groups, (2) formation of clusters to classify observations into groups, and (3) comparison of clusters to understand how they differ. *Multidimensional scaling*, also known as perceptual mapping, is often used in conjunction with cluster analysis to transform respondent judgments of preference into distances represented in multidimensional space. If two particular entities are judged by

consumers, for example, to be the most similar compared with all other possible pairs of objects, this technique will position these two entities in a way that the distance between them in multidimensional space is shorter than the distances between any other pair of entities.

Geographers use multivariate analysis methods in both aspatial and spatial contexts. In an aspatial context, the variables being analyzed may, or may not, be linked by spatial location. In the former case, however, the analysis methods consider neither the locations themselves as explicit variables nor the effects of spatial correlation and spatial autocorrelation between the variable observations that arise from their relative locations. Conversely, in a spatial context, geographers use multivariate analysis methods to explicitly model the spatial relationships, possibly including hierarchical relationships, between location-based variables. These may comprise, or include, the locations themselves as variables. Marked and multivariate point pattern analysis, spatial regression models, geostatistics, geographically weighted regression models, and hierarchical linear models for spatial data are examples of such spatially explicit approaches involving multivariate analysis. Where the location-based observations represent area or lattice data, multivariate analysis methods may contend with issues such as the modifiable area unit problem, measuring spatial proximities between observations, and defining spatial hierarchies.

MULTIVARIATE MAPPING

Multivariate mapping is the visual exploration of multiple attributes using a map or data reduction technique. More than one attribute can be visually explored and symbolized using numerous statistical classification systems or data reduction techniques. Complex data relationships can be visually displayed using graphical symbols. Color encodings are used to represent spatial relationships in a given data set in a logical sequence and interpretable format. To successfully communicate these complex spatial relationships, serious attention must be paid to human cognitive factors and perception. In practice, most small-scale data sets are usually displayed using graduated colors, graduated symbols, proportional symbols, dot density, bar charts, and stacked charts, among others. More recently, large-scale data sets have been represented using more complex data reduction techniques.

A set of visual variables (e.g., texture, orientation, color, size, shape, arrangement, and pattern) is available to facilitate the display and cartographic representation (symbol encoding) of multiple attributes. However, thoughtfulness in terms of map design, organization, and presentation of final results is required; symbols must be logically organized in a sequence that provides visual clarity so that the information can be easily decoded; and more important, the information must be successfully displayed and effectively communicated to the intended audience. Choosing colors can be quite challenging, but recent work by Cynthia Brewer has resulted in a very helpful guide to choosing a color scheme.

Examples from a geovisualization course are provided to illustrate the concept of multivariate mapping. In this course, students explored two data sets: (1) the first set depicted the relationship between murder rates and families in poverty in selected cities of the United States and (2) the second set depicted housing ownership covering a period from 1900 to 2000. The examples demonstrate the analysis of the covariation among variables within and between the two data sets with the intent of simplifying and visually displaying selected variables.

The use of multivariate mapping allows uncovering of the underlying relationships in data,

developing study hypotheses, and the description of complex spatial relationships. From the analyses of the two data sets, three study hypotheses were defined:

1. There is a spatial association between increased murder rates and the percentage of families living in poverty in selected cities in the United States.
2. Murder rates are higher in cities located in the East Coast than in cities located elsewhere in the United States.
3. Housing ownership is closely associated with economic expansion and prosperity.

In Figure 1, several plots are presented to illustrate a few variables that may influence murder rates in the United States. The upper panel in Figure 1 has a map, a histogram, and a table. The histogram is used to represent and explore the distribution of the young adult population at a county level. The table summarizes high murder rates, while the choropleth map is overlaid with a proportional symbol map to evaluate whether there is a visual association between murder rates and potentially related variables. A subset of young adults (ages 18–29) is explored together with the murder rates. The six divergent classes are symbolized using a ColorBrewer color scheme, with areas shown in red having the highest numbers and areas in blue having the lowest. In this multivariate map, graduated colors and proportional symbols have been used to represent murder in relation to young adults. From this map, we can infer that the West and Midwest have a lower number of young adults. The red area appears to be more concentrated in the central/eastern side of the United States. There is no apparent visual association between cities with the highest murder rates and cities with large populations of young adults. The lower panel in Figure 1 has a scatter plot, and a dot density map is linked, with proportional symbols representing different murder rates. This plot shows only a very small relation of young adults and population density to increased murder rates, and the highest murder rates appear in areas of high population density. The plot uncovers the fact that in some cities, such as those located in

Mississippi and Alabama, high murder rates are not necessarily associated with high population density. This demonstrates that association does not imply causality.

Figure 2 shows a choropleth map linked with stacked charts exploring the relationship between murder rates and families in poverty in selected cities of the United States. Combining a choropleth map together with charts allows the reader to better understand and interpret the data and their spatial patterns, which may provide fundamental clues about the data. Also, new spatial relationships between different attributes can be recognized and further explored.

Figure 3 shows the spatial distribution of the housing ownership rates over the past 100 years for the contiguous 48 states. Each state in the chart map has a bar graph that shows the corresponding rates of housing ownership over 100 years. By placing 10 stacked bar graphs on the states, we can spatially compare and contrast decreases and increases over time. Four

potential trends were identified and are displayed in this figure. Possible spatial variations in housing ownership can be explained by the Great Depression, World War II, and the resulting “baby boom,” all of which made a big impact on the housing ownership rates of all the states. Housing ownership rates are the highest in the midwestern, southeastern, and northeastern regions of the United States in the year 2000. Because of the economic depression and World War II, housing ownership rates decreased from 1930 to 1940 and climbed drastically from 1940 to 1950 due to economic expansion and prosperity in the post–World War II period. It would be interesting to see what will have happened in the decade following the 9/11 attacks and the subsequent war on terrorism. Based on past trends associated with World War II, we can hypothesize that U.S. housing ownership rates will decrease between the years 2000 and 2010, in part due to a shrinking economy and increased national debt.

The Red Ovals

These states which are located along the west coast and the Northeast exhibit the most stable housing ownership rates. There was a slight decrease in 1920 and 1940. But over the past decade, these states showed only a slight increase in ownership.

The Blue Oval

The general trend of these states has been a steady increase in housing ownership over the past 100 years. In contrast to many of the other states, these states showed a small increase in ownership during the 1930s.

The Green Oval

In the Midwest, there was a decline in the rate of housing ownership from 1900 to 1940. Specifically, the Dakotas of the north showed a strong rate of decrease. These states have shown a general increase over the past 60 years, but many have not risen past their 1900 levels.

The Yellow Oval

These states had a very slight decrease around 1930–1940. Then, the ownership rates increased from 1950 to 1980. The 2000 rates are nearly double that of 1900.

Figure 3 Housing ownership in the United States covering the period between 1900 and 2000

In summary, these examples demonstrate how to effectively combine different types of symbols and successfully communicate the complex patterns depicted in multivariate mapping.

MUSIC AND SOUND, GEOGRAPHY OF

The first systematic scholarly studies of music in geography were conducted by cultural geographers in the late 1960s and 1970s. These efforts were largely limited to examining music lyrics for their geographic content. Location and the evocation of attachment to these places is, indeed, one important aspect of the geography of music, but the subfield of music geography has become more

sophisticated in the intervening decades. The current focus is not only on the geographic significance of lyrics but also on the origin and diffusion of disparate musical styles, the geographic variations in consumer demand for various genres and artists, and the enormously important music industry, which produces, markets, and distributes these artistic endeavors.

Prior to the invention of the phonograph in the 1870s and the radio broadcasting of music in the 1920s, music was a purely oral (and aural) tradition that was ephemeral. Recording technology allowed music to become an important material artifact of a particular culture. Recording equipment made it possible for “song catchers” such as John and Alan Lomax to scour the hills and hollows of Appalachia in the 1920s and 1930s in search of and to record folk songs and ballads in the Celtic tradition and to establish the linkages between the new world and the old one left behind. Because of the dominance of the Berkeley School of cultural geography, folk music traditions dominated these geographic studies, and popular modern music was slower to gain a foothold in geography vis-à-vis other disciplines interested in music.

In the 1960s and 1970s, cultural geographers also became interested in the origin and diffusion of popular culture and its associated music. Larry Ford, for example, suggested that the various genres that made up contemporary music (e.g., rock-and-roll, bluegrass, country and western, gospel, blues) could be used pedagogically to illustrate and enliven discussion of geographic concepts such as culture hearths and diffusion mechanisms. Musicologists with an interest in geography examined the place names mentioned in popular country music lyrics, noting that the two states mentioned the most frequently (i.e., Tennessee and Texas) were also the states of origin of the greatest number of members of the Country Music Association. Geographic variations in the melodic elements of the music that would be of interest to musicologists were, however, largely ignored, perhaps because few geographers studying the subject were themselves well versed in the field of musicology.

Coincident with the “cultural turn” in economic geography in the late 1980s, there arose an interest in music geography among a different set

Four musicians performing at the Mountain Music Festival, Asheville, North Carolina, 1930s. This image is one of 400 photographs made in the course of sound-recording expeditions carried out between 1934 and ca. 1950 by John Avery Lomax, Alan Lomax, and Ruby Terrill Lomax, for the Archive of American Folk Song. The photographs depict African American, Mexican American, and white musicians, singers, and dancers, primarily in the Southern United States and the Bahamas. In addition to posed portraits, the images show musicians performing in various settings: at home, in a concert, and during prison labor outdoors.

Source: Library of Congress, Prints & Photographs Division, Lomax Collection (LC-DIG-ppmsc-00442).

of geographic scholars. Economic geographers such as Andrew Leyshon and Allen Scott mainly focused on the corporate aspects of the music market (e.g., the geographic consequences of corporate mergers and acquisitions in the recording industry). Music was a multibillion-dollar culture industry that was driving our consumerist culture. Those economic forces were of more interest to this new set of scholars than the more descriptive aspects that interested cultural geographers two decades earlier. The music industry displayed a tendency toward overproduction (e.g., too many musical acts signed to recording labels, too many records released that did not allow the labels to recoup their costs) as a result of uncertainty in the marketplace. Today, researchers such as Andrew Leyshon struggle to come to grips with the geographic consequences of changes in the demand side of the music industry, such as the downturn

in compact disk (CD) sales, after an initial surge in sales caused by the switch in recording medium from vinyl and cassette tape to CDs, and the increase in mp3 downloads—both legal and illegal. On the production side, geographers have also begun to focus on the geographic implications of home studios (i.e., less expensive and more ubiquitous digital technologies that are replacing older and more expensive analog versions). Still to be thoroughly researched is the seeming rise of independent labels and nontraditional outlets for bringing new musical acts to the attention of the public (e.g., MySpace pages, YouTube videos).

The “new cultural geography” also has had an impact on what aspects of music geographers are examining. Lily Kong, for example, examined the impact of music on national identity in Singapore. Sara Beth Keough examined the spatial impact of

a political decision by Canada to decrease the stranglehold (i.e., cultural hegemony) of the United States by requiring radio stations playing music to devote a considerable percentage of their airtime to playing Canadian music. In an ironic twist, Keough noted that playing the traditional Celtic music on the island of Newfoundland meets the Canadian content rules but reinforces the separatist nationalistic pride of Newfoundlanders, who voluntarily gave up their independence to become part of the Confederation in 1949.

Both cultural and economic geographers have been interested in musical scenes, the places where “the next big thing” in modern music might arise. John Connell and Chris Gibson explore the development of these scenes in places that were previously not known as musical hotbeds (e.g., the Dunedin sound in New Zealand, the grunge music scene in Seattle) but that leaped to the fore because of modern technologies. They examined as well the infrastructure necessary to create a musical scene, including recording studios, clubs and live venues, and often a university-based arty crowd that tolerates and even demands musical experimentation and innovation. Ola Johansson and Thomas L. Bell researched what constitutes a successful tour or circuit for different genres of modern rock music in North America.

Connell and Gibson have not confined their studies to music per se but have extended the aural aspects to include ambient sounds that are representational of particular cultures, such as the CDs of the exotic sounds of kookaburras and didgeridoos sold in tourist shops rather than record stores in Australia. Ambient sounds are used to evoke moods, to relieve stress, and to induce restful states. Even sounds associated with the city (e.g., blaring horns, high-pitched sirens, noisy jackhammers) may evoke pleasant memories for former city dwellers in the same manner that familiar odors and aromas stimulate memories through the olfactory sense.

Another important aspect of the geography of music and sound concerns a more problematic aspect of the aural landscape—soundscapes that are not particularly harmonious, melodic, or pleasant—that is, sounds that are not music but rather noise. A cacophony of discordant sounds can damage the eardrums if they are too loud, and they just as surely diminish the quality of life, as

does visual blight. Likewise, obnoxious soundscapes affect our feeling about places. Because geography is an inherently visual discipline, more research has been conducted on the visual aspect of the human experience than on images of the phenomenal world formed through our other senses. Future research should examine these non-musical soundscapes to a greater extent than has been done in the past. A great deal of research on tactile mapping has been conducted to enable the sight impaired to negotiate their environment, but more research is needed to sensitize those with normal hearing to the life-worlds of those with severe hearing loss. Perhaps the most ironic aspect of the soundscape is the manner in which many attempt to drown it out by listening to their private world of music and sound through the earbuds of their iPods and similar devices, all the while ignoring the sounds of nature or even traffic all around them. Is this privatized aural insularity a good thing for reinforcing a sense of community? Surely it is an important topic to research.

N

NATION

The term *nation* has multiple meanings. It is frequently employed to refer to a country, as in sentences such as “France is a nation” and “Snow is falling across the nation’s midsection.” It also is used as a synonym for large social groups such as the French, Arabs, or Cherokees. The term *nation* generally refers to large social groups; however, it is also used interchangeably with terms for other large social formations such as ethnic groups, nationalities, races, and tribes. These concepts also overlap as many nations are multiethnic, multiracial, and multitribal. Despite similarities in meanings, nation has its own distinct meanings and origins. It derives from the Latin *nationem*, meaning “breed or race,” which itself stems from *nasci*, “to be born.” When the word *nation* entered the English language in the 13th century, it reflected this original meaning by referring to a “blood-related group.” However, by the 17th century, nation was applied to inhabitants of a country. The use of the word *nation* today echoes one or both of these meanings.

The meaning of nation was expanded and shaped by the Enlightenment and then the Romantic period. The Enlightenment *figures* such as John Locke and John Milton emphasized the rights of individuals with governance dependent on the free consent of the governed. Jean-Jacques Rousseau accepted that individuals’ rights were

essential, but he believed that individual rights could best be protected through group membership because collective groups best provided security to individuals. Therefore, nations were viewed as individuals bound together for collective security rather than by common cultural characteristics. Because states existed to provide security, it was crucial for individuals within states to develop an “ardent love for the fatherland/motherland” so that states could perform their mission of providing security. These ideas fit well with the emerging modern state, whose inhabitants (i.e., citizens) were then seen as a nation bound together by the state.

Rousseau’s preoccupation with security meant that he believed that national membership was best determined by the need to maximize states’ abilities to ensure the security of their citizens. Accordingly, Rousseau believed that the size of nations should be no larger than that which could be sustained by the available natural resources in a territory. Similarly, security also was achieved by the location of states’ boundaries along physiographic features such as mountain ridges and rivers because they were seen as the most easily defensible. Therefore, rather than grouping people together by common cultural characteristics, Rousseau believed that national membership was defined by groups’ optimal sizes relative to the available resources and the location of the individuals within these easily defended boundaries. Today, it is accepted that nations require resources

and need to defend themselves; however, few believe that natural resources determine the existence and the size of nations and who belong to them. However, Rousseau so thoroughly intertwined national identity with the natural world that he and those who built on his ideas believed that nature determined the number, sizes, and appropriate territories of nations.

Later romantics such as Johann Gottfried Herder deemphasized the role of individuals and focused instead on the collective group, *das Volk* (the people), bound together by shared culture, most notably language, religion, and history. Romantics believed that each language was “a currency of thought.” Therefore, to bond together into a nation, individuals had to speak the same language. Vernacular languages were essential because each one embodied a nation’s culture, beliefs, and values, molding its members’ thinking and behavior in a way not completely translatable into other languages. Nature also was seen as a determinant of national identity because it was believed to be a force that shaped culture, including language. This notion was reinforced by environmental determinism as it grew in the 19th century. Thus, language and physiographic regions were seen to go hand in hand and were viewed as mutually reinforcing. For example, Irish nationalists frequently asserted that nature (which often includes God) created an island called Ireland and, therefore, nature intends for one people (i.e., the Irish) to live there under the governance of a single Irish state. This belief is expressed in Article 2 of the Constitution of the Republic of Ireland, written in 1937: “The national territory consists of the whole island of Ireland, its islands and the territorial seas.” Similarly, French nationalists developed the belief that France was naturally bounded by the Atlantic, the Pyrenees, the Alps, and the Rhine River. For example, Buache de la Neuville wrote in 1791 that France’s boundaries should be fixed according to “the natural division of the Globe formed at its origin by the Creator.” By the middle of the 19th century, the concept of natural boundaries provided the French public with “a lesson of sacred union” and a sense of historical continuity.

In the late 19th and early 20th centuries, the idea of race became entangled with these

romantic conceptions of nation, essentially making the two synonymous for a time. Maps too reinforced the unification of these concepts by depicting the spatial distributions of “races,” though they were basically the same as maps of nations defined by languages. An example is seen in a *National Geographic* map titled “The Races of Europe.” It appeared as a supplement in the organization’s December 1918 issue of its magazine, which was devoted to the topic of race. The union of race and nation reached its culmination with the Nazis and likewise was discredited, but their association still lingers as some see nations as somehow genetically based.

In the latter half of the 20th century, scholars recognized that nations cannot be easily defined by objective criteria such as language and religion. A one-to-one correlation between languages and/or religions does not exist. Also, many nations formed before their members spoke a common language. For example, the historian Eric Hobsbawm points out that only about 50% of the French spoke French in 1789 and only 12% to 13% spoke it correctly by the language standards of the time; only 2.5% of Italy’s population spoke Italian regularly in 1860. Hobsbawm also notes that many nations also predate their traditions. These traditions may strengthen the bonds of unity, but they clearly were not the medium for the initial bonding. Hobsbawm coined the phrase *invented traditions* to highlight the true role of traditions to nationhood. Because many nations consciously and deliberately cultivate cultural characteristics to distinguish themselves from those they consider to be “others,” he believed that it is not objective criteria but subjective ones that define nations. Along these lines, Benedict Anderson coined the term *imagined communities* to refer to nations because their distinctiveness is based on their members’ imaginations of themselves and others.

Academics offer differing opinions concerning the true age of nations. Anthony Smith divides these opinions into four paradigms: primordialism, perennialism, ethnosymbolism, and modernism. Primordialism insists that nations are as old as humanity and are natural, organic, and biological entities. Perennialism accepts that nationalism is a modern political force but argues that

most nations are old while conceding that some formed more recently. Ethnosymbolism believes that old identities influenced the development of modern nations while admitting that many memories and cultural practices are subjective and some are fabricated. Finally, modernism argues that nations formed only since the French Revolution. Modernism has five subtypes based on the differing causes of social formation: socio-economic, sociocultural, political, ideological, and constructionist.

Despite differing perspectives on the age of nations, the concepts of nation, ethnic group, race, and tribe clearly draw on many of the same cultural characteristics, which explains their blurred boundaries and also why they are interused as terms. However, their differences stem in part from their varying emphasis on these characteristics. In particular, nations stand apart by a strong sense of self-awareness and the desire for self-governance. Some ethnic groups and races exist because they are classified as such, often by academics or governments, though those grouped in such categories may not be aware of or subscribe to these identity classifications. In contrast, nations have a strong sense of solidarity and a belief that they need their own governments so that they can protect and cultivate their identities. Nations believe that only they know what is best for themselves. In many ways, nations are politicized ethnic, racial, and tribal groups. However, it also means that the desire for self-governance can be shared by individuals of different ethnic, racial, and tribal backgrounds, in turn explaining why some nations are multiethnic, multiracial, and multiracial.

The expectation of self-governance requires territory because policies and laws are tied to territory, though they are ultimately directed at people. The links between nations, their governments, and the territories in which their laws apply are manifested in the nation-state ideal: the belief that every nation must have its own state and within every state a single nation. This ideal is best reflected in a minority of countries, notably in European ones where the ideal was conceived. It poorly describes countries that were most recently European colonies. Overall, the nation-state ideal drives nationalist projects and much conflict around the world.

Some academics argue that not all nations have self-government and point to examples such as Palestinians, Kurds, Basques, and Scots. However, these groups are by no means content with their lack of independence and seek it as a primary goal. At the same time, these examples show that not all members of a social group develop a national identity at the same time. Those who do call for self-governance often identify themselves as nationalists.

In summary, Symmons-Symonolewicz (1985) provides a nuanced definition of nation:

A territorially-based community of human beings sharing a distinct variant of modern culture, bound together by a strong sentiment of unity and solidarity, marked by a clear historically-rooted consciousness of national identity, and possessing, or striving to possess, a genuine political self-government. (p. 221)

NATIONAL AERONAUTICS AND SPACE ADMINISTRATION (NASA)

In 1958, the National Aeronautics and Space Administration (NASA) was established by President Dwight Eisenhower partially as an extension of the National Advisory Committee on Aeronautics (NACA) and also in response to the Soviet Union's first satellite launch. Under the National Aeronautics and Space Act, NASA is a federally funded public agency with four primary mission directorates:

1. Direct the development and validation of exploration systems
2. Improve modern aeronautics
3. Create and maintain space operations
4. Explore the Earth, solar system, and universe

In accordance with these mission directorates, NASA is responsible for funding projects that advance each of these goals. Two of the first successful projects were the Mercury and Gemini missions, which enabled NASA to become the

first agency to place a human on the moon. NASA also funded programs that led to the development of the first communication and weather satellites. While NASA has greatly expanded knowledge about space with projects such as the Hubble Space Telescope and exploration missions to Mars and other planets, it has also made significant contributions to the exploration about Earth and its systems.

NASA has launched and developed several Earth observation satellites and instruments that record data specifically related to Earth's systems and geography. One of NASA's first successful Earth-orbiting missions is *Terra*. This satellite has five onboard sensors that record data that a multitude of scientists are using to study interactions between Earth's systems. Another successful mission is *Aqua*, a satellite with several onboard sensors that record data about Earth's surface that can enable scientists to observe and understand how Earth's water cycle has changed and is changing over time.

All NASA satellites have components developed by NASA, but some also have instruments and components that were developed with the cooperation of other space and government agencies throughout the world. Some of these missions are Jason-1, Landsat, and Tropical Rainfall Measuring Mission. There are also NASA-developed instruments and flight technology on board other agencies satellites, such as the QuikScat instrument that records wind speed and direction over Earth's land masses and oceans but resides onboard of Japan's Midori mission. Landsat is another mission that uses several satellites to create digital images of Earth by instruments developed through the collaboration between NASA and the U.S. Geological Survey.

The images and data produced from NASA missions have advanced the remote sensing discipline by producing high- and low-resolution imagery and data of Earth and its systems that has also contributed dramatically to the advancement of science in understanding, observing, and predicting Earth's processes and characteristics.

NATIONAL CENTER FOR GEOGRAPHIC INFORMATION AND ANALYSIS

The U.S. National Center for Geographic Information and Analysis (NCGIA) was established in 1988 at the University of California, Santa

Barbara; the State University of New York at Buffalo (the University at Buffalo); and the University of Maine. Funded from 1988 through 1996 by the National Science Foundation (NSF) following an open competition, the center continues under a collaborative agreement between the three institutions. The center's mission is to conduct research in geographic information science and to undertake associated educational and outreach programs.

By 1986, it had become clear that geographic information systems (GIS) were a growing computer application with abundant uses in a range of human activities, including science. At NSF, the officer newly responsible for the Geography and Regional Science program, Ronald Abler, saw an opportunity to promote the establishment of a research center that would act as a focus for research and education in this new field. A solicitation was developed that suggested five themes for research: (1) spatial analysis and spatial statistics, (2) spatial relationships and database structures, (3) artificial intelligence and expert systems, (4) visualization, and (5) social, economic, and

institutional issues. Eight teams responded to the solicitation issued by NSF in early 1987, and the project was awarded to the three-site consortium led by University of California, Santa Barbara.

Two key activities immediately served to characterize the new center and its proposal. First, research was to be conducted as a series of initiatives, each one lasting between 2 to 3 years and focusing on a specific topic within the five major themes. Each initiative would begin with a specialist meeting that would bring 20 to 40 scholars together to review the state of the art and develop and prioritize a research agenda. The initiative would proceed through activities both inside the center and in the broader community and would end with presentations on research results at a major conference and a final report. The first specialist meeting was held in December 1988 on the subject of the accuracy of spatial databases, and to date, more than 40 topics have been investigated.

The second activity was developed in response to a perceived lack of textbooks and other teaching materials in the growing field of GIS education. A core curriculum was designed as a collection of 75 sets of prototype lecture notes, and authors were recruited to prepare drafts. During the 1989–1990 academic year, roughly 100 instructors agreed to teach part, or all, of the curriculum, and their experiences were used to prepare a final draft that was published in 1990. More than 1,500 copies of the curriculum, assembled in three large binders, were distributed in the following years and became a foundation for the rapid expansion of worldwide education in GIS.

NATIONAL COUNCIL FOR GEOGRAPHIC EDUCATION

The National Council for Geographic Education (NCGE) is a professional organization whose mission is to enhance the status and quality of geography teaching and learning. The NCGE has played an active role in advancing the place of geography in the American curriculum through workshops, publications, and grant-supported projects targeting underserved groups, research in geographic learning, use of technology, and in the preparation of teachers to introduce the subject of advanced-placement human geography.

The NCGE was established in 1915 by George J. Miller, a professor of geography at the State Teachers College of Mankato, Minnesota. Originally known as the National Council of Geography Teachers, the organization adopted its present name in 1956. The NCGE maintains an open membership policy, welcoming members from all levels of geography education, including students, K–12 teachers, college and university faculty, corporations and libraries, and individuals in the public and private sectors who are interested in geography education. The membership is mainly from the United States, representing every state and the District of Columbia, as well as the territories. The organization also has international members, especially from Canada.

Member services include a bimonthly newsletter, *Perspective*; a peer-reviewed journal, the *Journal of Geography*, published six times per year; and a second journal oriented toward K–12 members, *The Geography Teacher*, published four times each year. The NCGE's Pathways publications series, initiated in 1991, includes more than 30 volumes that address topics of

interest to geography educators relating to research, regional and thematic content, and instructional strategies.

The NCGE sponsors an annual conference at locations across the United States. Meetings have occasionally also been held outside the United States, most recently in Canada and the Dominican Republic. Annual conferences afford members an opportunity to exchange ideas, practice new techniques, and share lessons in a collegial forum. Field trips and plenary sessions in which noted geographers speak are also an important part of the annual conferences, as are the NCGE-sponsored special interest groups, such as the Supplemental Instruction e-mail discussion group, that allow educators with common interests to share ideas and seek solutions to classroom challenges.

The NCGE recognizes excellence in geography education through a multifaceted awards program. The organization's highest honor, the George J. Miller Award, is named after the organization's founder and presented to one geographer each year for distinguished contributions and service to geography. In addition, outstanding teachers, at both the K–12 and the college level, are recognized, and publications and other media, both within and beyond the discipline of geography, are highlighted.

The NCGE is led by officers and an executive planning board elected by the membership. In 2007, the organization's central office, headed by an executive director, was relocated to Washington, D.C.

NATIONAL GEOGRAPHIC SOCIETY

The National Geographic Society has a wide-ranging impact on how Americans—and the world—understand geography, tying its mission of diffusing geographic knowledge to human fascination with exploration, travel, and adventure. The society both represents and shapes cultural understandings of geography in the United States.

The Washington, D.C.-based National Geographic Society was founded in 1888, in an era of “explorers’ clubs,” with 33 original members that included geologists, bankers, explorers, and meteorologists. Gilbert Grosvenor, the magazine’s first editor, is credited with transforming the magazine from a jargon-ridden technical review to the colorful publication it is today. Under Grosvenor’s reign, *National Geographic* found its footing in eyewitness, photograph-heavy accounts of faraway places. Society projects have included research by Louis and Mary Leakey on the origins of humans in Africa, Jane Goodall on chimpanzees in Tanzania, and Robert Ballard on the sunken *Titanic*. Today *National Geographic* magazine has a circulation of 8.5 million and is published in more than 30 languages.

National Geographic is an internationally known magazine that has long served to educate its readers about distant places. At times, however, the magazine has been as reflective of Western culture as it has been educative. In its early years, *National Geographic* stories carried an imperialist tone common to explorers’ clubs of the day. In hindsight, the bare-breasted photos of women in “exotic” locales are seen as voyeuristic, and the magazine’s mid-20th-century photography is criticized for being more aesthetic than enlightening. In the 1960s and 1970s, the magazine moved in a more realistic and politically charged direction. While this angle created internal dissent about the society’s mission, features such as those illustrating urban conditions in the United States or the impact of apartheid in South Africa ultimately became an important part of *National Geographic* as it is known today.

A key turning point in the National Geographic Society’s history was its December 1970

magazine titled *Our Ecological Crisis*, in which authors took a stand against pollution. In the following years, the society has focused on conservation and increasing environmental awareness while continuing to showcase beautiful locales around the world.

While the magazine is the cornerstone of the National Geographic Society, its educational mission has expanded over the past century to include many other forms of media. Its membership, together with its other enterprises, has funded more than 8,000 field research projects. These and other geographic findings have been profiled in society lectures, books, television specials, and on the Internet, where the National Geographic Web site gets 12 million visitors per month. In recent years, the society has focused on improving geographic literacy through educational alliances, grants to schools, and the nationally televised National Geographic Bee.

NATIONALISM

Nationalism is a term generally used to describe either the attachment of a person to a particular nation or a political action by a group of persons to achieve statehood (or national self-determination). While there is debate about the origin and antiquity of the idea of a nation, the political manifestation of national identity as nationalism is widely accepted as a relatively modern concept. As the state became the primary

locus of sovereignty in the 18th and 19th centuries, it became increasingly important for ruling elites to construct a narrative that provided the often culturally heterogeneous populations that inhabited the state territory with a single identity. Depending on the circumstances of state formation, this identity could be voluntary and founded on adherence to ideology and institutions, or it could be constructed as involuntary—a function of genetic inheritance with the individual unable to leave the collective or to join except through birth. Nationalism became an increasingly important political ideology in the 20th century as the existence of a distinct national identity became a necessary and—eventually at the end of World War I—a sufficient condition for the creation of a sovereign state. The rise of superpowers and intergovernmental bodies such as the European Union modified concepts of state sovereignty in the latter part of the 20th century, yet nationalism has remained a potent political force, as seen in the breakup of the Soviet Union, Yugoslavia, and Czechoslovakia, as well as in the substate nationalisms of Spain, Britain, and Belgium.

Types of Nationalism

There are many typologies of nationalism; one of the most useful being Hans Kohn's two-part distinction between Western and Eastern or civic and ethnic nationalism. This typology was expanded by Liah Greenfeld to include a third category, collective nationalism, which can take either ethnic or civic forms.

Civic nationalism was the first to develop and is represented by the English model of national identity as a rational choice for those desiring self-determination and individual liberty. The nation is composed of individuals who occupy a common territory and willingly form bonds based on ideology and on shared political institutions. This model is flexible and inclusive, permitting membership to anyone who voluntarily resides in the territory and recognizes the institutions, iconography, and ideology of the group. The goal of civic nationalism is generally statehood, as it is only at that level of sovereignty that ideology can be translated into fully independent institutions. Civic nationalism embodies the

concept of sovereignty of the people; the nation cannot exist without the collective will of the people who support it. This model began in Tudor England but is best represented in the formation of the United States, where the desire for self-determination was largely based on the ideological drive toward greater individual liberty and the need to create new institutions to enshrine popular sovereignty. After two centuries of absorbing immigrants, who identified with countless different language, religious, ethnic, and racial groups, the very strong nationalist ethos of the United States remains almost entirely based on attachment to iconography and institutions.

Collective nationalism is an extension of civic nationalism that grants the nation itself an identity. The nation is created by the will of the people, and once created, it acquires a will and identity of its own that takes priority over the will of individuals. When applied in the context of civic nationalism, as in the case of France, this creates a great deal of political ambiguity, acknowledging the freedom of the individual while simultaneously submerging that freedom in the greater will of the “nation.” Such nationalism generally emerges as an elite caste attempts to preserve its status while transmitting its version of national identity to the masses by indoctrination, as in the case of France, where the bureaucratic elite came into being in the wake of the French Revolution.

Collective nationalism, however, works best when paired with ethnic nationalism. The contradictions of collectivism versus self-determination disappear when there is no choice. Ethnic nationalism assumes that national identity is inherent, and it emerged as a political philosophy with the rise of cultural nationalism in the 19th century. The principal philosophical underpinnings of ethnic nationalism come from German writings on national identity in the late 18th and early 19th centuries, particularly the works of Herder and Fichte. They equated the German language with the new concept of *das Volk* (the people), which in turn created the German nation. Membership in this group was not voluntary; anyone who spoke German was part of *das Volk* and therefore part of the nation. By extension, anyone who did not speak German, was not part of *das Volk* or the nation and could be excluded. By its

very nature, ethnic nationalism is involuntary and exclusionary—it compels all those who fit the objective criteria of the nation to be members and excludes all those who cannot meet those criteria. Ethnic nationalism spread rapidly from Germany to Russia and much of Central and Eastern Europe and became the most common model of nationalism in the 20th century. The involuntary nature of ethnic nationalism combines easily with collectivist nationalism, and the combination can often result in totalitarianism or majoritarianism with fatal consequences for those excluded from the nation. From the Holocaust to Stalin’s ethnic deportation programs, to ethnic cleansing in Serbia, millions have died as a result of this marriage of ethnic nationalism with political will.

A History of Nationalism

Although advocates of the primordialist theory of nationalism would disagree, it is widely contended that nationalism is a modern construct dating back to the 18th century at the earliest, although Liah Greenfeld convincingly dates the first appearance of modern nationalism to the construction of the English identity in Tudor England during the 16th century. That identity was strengthened in the 17th century during the English Civil War and the subsequent Calvinist period that equated Puritan England with ancient Israel and upheld the idea of the English as God’s chosen people. Later in the century, the rise of new intellectual philosophies of John Locke and Thomas Hobbes and the literature of authors such as John Milton focused English national identity on ideas of liberty, individualism, and the importance of popular sovereignty. In the 18th century, those ideas were to lead to the first true political expressions of popular sovereignty in the American and French revolutions, both of which tied together national identity, individual liberty, and the creation of the sovereign state as the ideal container for that identity.

In the early 19th century, however, partly as a response to the rational, humanist nature of French nationalism, a new form of national identity emerged, that of cultural nationalism. This movement emphasized the bonds of language, perceived ethnicity, race, and bloodline and was profoundly emotional in nature. Rejecting the

ideological and voluntary basis of the French and English national models, this form of national identity was entirely determined by genetics and birth. One can neither voluntarily join this national group nor leave it; national identity is held to be imprinted through bloodline, race, and ethnicity and is expressed through language and religion. Thus, the Alsace-Lorraine region of France was French by choice (the inhabitants having taken an active part in the French Revolution) until the newly formed German Empire demanded that the territory be ceded as part of the settlement of the Franco-Prussian War. The basis for the claim was genetic, the people of Alsace-Lorraine spoke German, and therefore, they were part of the German nation and should be part of the new German state. Throughout the 19th century, the Imperial powers of Europe found themselves confronted by increased national self-awareness in their subject peoples. From Ireland to Serbia and from Norway to Greece, literature, music, mythology, art, and language were used to define culturally distinctive national groups that could then press for self-determination.

The 19th century also brought technological changes that greatly aided the formation and maintenance of these new national identities, especially among the ordinary population. The advent of compulsory public education provided the stage for states to promote their vision of the nation while simultaneously becoming a battleground for substate nationalities attempting to preserve and promote their language and culture in the face of the drive toward homogeneity that characterized the emergence of state nationalism. At the same time, the development of mass production and the mass media, at first in the form of newspapers and then in magazines, posters, and radio, permitted the widespread dissemination of these new ideas about national identity.

At the end of World War I, the disintegration of the Ottoman, Austro-Hungarian, and German Empires marked the apogee of state nationalism as virtually the entire postwar territorial settlement was based on Woodrow Wilson's 14 points, which explicitly set out national identity as the basis for state formation. Unfortunately, it was virtually impossible to construct states that precisely matched the territorial boundaries of

nations that had been created in the preceding century. As a result, multinational states were created where majority national identities were able to impose their vision of the nation on the entire population. It is this drive toward a single homogeneous national identity that is known as state nationalism, and it is virtually universal among modern states. Even in the United States, where national identity is based on voluntary attachment to ideology, 19th- and early-20th-century attempts to eliminate Native American languages by educating indigenous children in state boarding schools demonstrate a desire to impose cultural conditions on the American national identity. Likewise, in the Soviet Union, a multination, multiethnic, multilingual, and multireligious collection of territories founded in 1922, commitment to the ideal of communism was the professed litmus test of national belonging, but in practice, the imposition of the Russian language and culture was the ongoing program of state nationalism.

As decolonization of Asia, Africa, and the Middle East proceeded in the interwar and post-World War II periods, state nationalism again dominated. New states, their borders drawn by colonial powers and again rarely able to conform to the stated ideal of containing individual nations in their own states, readily embraced state nationalism where the iconography and identity of the majority nation was imposed on the often unwilling minorities.

In the long term, however, it appears that state nationalism is not universally successful. Spurred by the discrimination and marginalization inherent in state nationalism, those unwilling minorities have increasingly engaged in peripheral nationalism, or the desire for the creation of substate nations to achieve self-determination and statehood. Released from totalitarian control or simply provoked by the perceived ongoing discrimination substate nations across Europe, Africa, and the Middle East in particular have reasserted their claims to self-determination in the wake of the Cold War.

In 1990, Eric Hobsbawm wrote of being able to envision the end of nationalism as a viable political creed. Over the past 20 years, however, political nationalism with the goal of creating new nation-states has flourished as the small nations of

Europe and the Soviet Union have enjoyed new political freedoms associated with the end of the Cold War and the rise of the European Union, which has begun to erode the state as the sole seat of sovereignty. Some of these nationalisms are civic—the Catalans and the Scots in particular base their claims for self-determination on the existence of distinct institutions. Many others are more inclined toward ethnic nationalism—a trajectory that has been headed off in some cases by membership in the European Union. However, in many countries, notably Russia, Serbia, Belarus, and others, indications of both collectivist and ethnic tendencies are evident in the manner in which the elites continue to manipulate history, culture, language, and propaganda to court the masses and marginalize any group that is not part of the constructed “nation.”

NATURAL GROWTH RATE

In demography and population geography, the natural growth rate (NGR) is the difference between birth rates (BR) and death rates (DR), that is, $NGR = BR - DR$. Along with net migration, natural growth rates are one of the two

fundamental components of demographic change. For the world as a whole, natural growth rates are the only measure of population change, although for any unit less than that both natural growth and net migration must be taken into account.

Historically, natural growth rates have been very low, often zero, and at times, when mortality exceeded fertility (such as during famines or plagues), even negative. Only with the Industrial Revolution and the concomitant reductions in death rates (not a rise in birth rates) did natural growth rates rise, leading to an exponential increase in the world's population level (Figure 1). Thus, rapidly growing societies are essentially a product of modernity. Thomas Malthus, the founder of the notion of overpopulation, observed the rise in natural growth in late-18th-century England to sound the alarm that such increases would offset any economic gains, although his conclusions were rendered incorrect by the exponential increases in productivity that industrialization generated.

Natural growth rates vary widely around the world (Figure 2) and reflect the multitude of social, economic, and political factors that shape the geography of birth and death rates, particularly wealth and poverty. Because mortality rates have been to a considerable extent equalized worldwide, the major variations in natural growth rates are mostly attributable to differences in birth rates. Such patterns are largely explainable by appeal to the demographic transition. Generally, the poorest countries have the highest birth rates, and thus the highest natural growth rates, as in parts of Africa and the Arab world. Frequently, rising incomes lead to lower birth rates and smaller families, as in Europe, North America, Japan, Australia, and New Zealand. In many economically developed countries, where death rates exceed birth rates, natural growth may be essentially stagnant (i.e., zero population growth) or even negative, as in much of Eastern Europe and the Soviet Union as well as parts of Southern Africa afflicted by the AIDS crisis, indicating that whatever population increase occurs is due entirely to immigration.

Overall, as global fertility rates have declined, so too has the average worldwide natural growth rate, which is widely expected to continue dropping

Figure 1 World population level, 7000 BC to AD 2000. The dramatic explosion in the world's population since the Industrial Revolution reflects the decline in mortality rates that it fostered.

Figure 2 Natural growth rates, 2007. Variations in natural growth around the world primarily reflect differences in mortality rates; some countries experience negative natural growth.

Source: Author.

Figure 3 World natural growth rates since 1950 and projected to 2050. Gradual declines in fertility worldwide have led, and are expected to continue to lead, to declines in the world's population increases.

Source: Author.

in the foreseeable future (Figure 3). Thus, whereas the world's natural growth peaked in the mid 1960s (around 2.3% annually) and dropped to 1.3% in 2007, it is projected to fall as low as 0.5% by the year 2050.

NATURAL HAZARDS AND RISK ANALYSIS

Human beings live on a restless, dynamic planet. Our settlements and livelihoods depend on Earth's variations and variability, past and present, in the form of geology, topography, climate, and the distribution of vegetation and freshwater. At the same time, these variations and variability pose potential threats, which are called natural hazards. Extreme movements in Earth's crust release

energy experienced as earthquakes, volcanoes, and tsunamis on Earth. Climate extremes such as hurricanes release gigantic amounts of energy. Heat waves, blizzards, and ice storms are other climate extremes. Floods and mass movements such as landslides, rock fall, and snow avalanches are more localized but can be very destructive and deadly, as are tornadoes and lightning strikes. Drought is a slow-onset hazard but nevertheless associated at times with great economic cost and displacement of people.

Hazards, however, are not in themselves a problem for humanity. Every day, many thunderstorms flash and rumble around the world in uninhabited areas and over the large surface of the planet covered by oceans. Ice, rock, and debris slides are a normal part of the erosion and deposition cycle, and many take place in uninhabited regions of Earth's mountains. To mention an extreme case, a sizable object (perhaps a meteor or comet) entered the atmosphere and exploded over Tunguska, Siberia, in 1908, flattening 80 million trees over an area of 2,000 square kilometers. But there were no human settlements. Had the event occurred over London or Paris, the outcome for humanity would have been quite different.

At the other end of a continuum of magnitude, even normal (statistically mean) values for some natural processes may endanger the health, livelihoods, and lives of people so poor or so marginalized by society as to live with little protection in highly exposed locations such as very steep slopes, in gullies, on temporary silt islands, or very near a river flood plain. In such cases, “normal” or “small” landslides, seasonal flooding, or the occasional “expected” rock fall may have catastrophic consequences for one or a few households while never being registered as a “disaster” for society.

Disaster Magnitude and Trends

The *Global Assessment of Disaster Risk Reduction 2009* of the United Nations (UN) reveals large human and economic losses to disasters triggered by natural hazards. Excluding deaths due to epidemics, some 8,866 events accounted for 2.3 million deaths in the period 1975 to 2008; economic losses in that period totaled US\$1,528 billion. Deaths were concentrated in low-income countries; while absolute economic losses (especially insured losses) were heavy in high-income countries, although low-income countries bore the brunt of economic damage when compared with their limited gross domestic product. In addition, losses are increasing.

Five of the disasters with the highest death tolls since 1975 have occurred during the recent period 2003 to 2008. These more recent events include 4 of the 10 disasters with the highest economic losses since 1975. Since 2004, the United States has lost US\$200 billion in six hurricanes. In that same period Japan lost US\$40 billion in two earthquakes, and China lost US\$30 billion in the 2008 earthquake in Sichuan.

Risk Analysis

Risk from such natural hazards is a function not only of the magnitude, frequency, and spatial extent of the event but also of specific people's susceptibility to loss, injury, or death. Susceptibility to harm is usually referred to as vulnerability (V) when its determinates are included. Vulnerability may be counteracted by individual and local capacity (C) for protective action and coping in

times of crisis and by protective actions carried out by larger entities such as the nation-state or subnational governmental actors, generally called mitigation (M). One can bring all these together in a useful mnemonic:

$$R = H \times [(V/C) - M],$$

where R is risk and H is hazard, V stands for vulnerability, C represents capacity for personal protection, and M symbolizes larger scale mitigation of risk by preventive action and social protection.

Vulnerability and capacity need to be seen in the context of the processes of marginalization and prejudice in society. All societies have within them groups of people who are stigmatized, marginalized, and excluded to one degree or another because of their perceived characteristics—health status and physical/mental abilities, gender or sexual orientation, age, ethnicity, caste, language, or religious affiliation. Exclusion may lead to situations in which residential location, occupation, income, access to information, and political representation might contribute to increased vulnerability to the impacts of natural hazards. However, such people should not simply be seen as victims. They are also frustrated potential participants in the process of risk reduction. They have knowledge and skills, yet few are included in planning and projects. In the United States, for example, according to a 2009 report by the U.S. National Disability Council, very few people living with disabilities have been asked what they need or want or how they can contribute to risk reduction. In many countries, women's and children's knowledge and capabilities are not recognized by professional emergency managers and planners despite the well-documented achievements by children and women. Social movements make the situation of the marginalized more visible, and some positive policies and practices have begun to find traction as expressed during the 2009 UN Global Platform for Disaster Reduction.

Ambiguity of the Term *Natural Hazard*

What should be obvious by now is that the term *natural hazard* is ambiguous. A possibly better term would simply be *potentially damaging natural events and processes*. More than 200 years

ago, Samuel Johnson refuted idealism by kicking a stone. Johnson's cry, "Thus, I refute it," must resonate with those whose fieldwork puts them in direct contact with natural hazards and their human consequences. The introduction of vulnerability in risk analysis never denies the reality of hurricane force wind. No one who writes about herders who have lost all their animals disputes the power of the sun baking the cracked soil. What natural sciences know about potentially damaging natural events and processes is vital and should be made available to those exposed to such threats. However, departing again somewhat from more conventional views, local knowledge of these processes is also important when it comes to understanding how people cope with natural hazards. People's experience of natural hazards is also a form of knowledge that has been given many names: *ethnoscience*, *folk ecology*, and *indigenous technical knowledge*.

Root Causes of Disaster Risk

What accounts for the degree of social vulnerability, capacity for personal protection, and level of state investment in social protection and preventive action? While detailed answers vary from situation to situation, there are always root causes that can be traced back through the history of control over resources in a particular society and how political power was divided and used. These root causes take particular forms as policy decisions and institutions react to economic, political, and demographic pressures. Focused in this way, historically established power relations (e.g., relations governing land tenure, access to capital and markets, and location decisions)—that is, the "root causes"—are translated by dynamic pressures into specific unsafe conditions: my building or my home under an unstable slope or you living in a zone of seismic activity and sending your child to a school that will likely collapse in an earthquake.

Power—its use and misuse—shapes how disaster risk is distributed socially and spatially. National scale politics defines winners and losers, and this despite substantial international encouragement for development of laws and institutions for reduction and management of disaster risk. There is a large gap between rhetoric and reality,

and this becomes even clearer when one explores the human rights implications and dimensions of disaster risk. So, too, violent conflict has very complex relations with natural hazards and disasters. People displaced by conflict may be forced to settle in locations prone to natural hazards. People caught up in a conflict are often less accessible to humanitarian agencies wanting to respond to the human impact of a natural hazard. Moreover, hazard events may exacerbate an existing conflict, as in Sri Lanka, or afford the occasion for belligerents to seek peace, as in Indonesia—both cases following the impact of the great Asian tsunami in 2004.

Links With Sustainable Development and Climate Change

Root causes of disaster vulnerability are also evident in the ways in which people exploit the natural environment. Possibly damaging natural processes may also take the form of "resources." For this reason, people have settled and farmed on the fertile slopes of volcanoes and in the alluvium deposited by floods for millennia. While this dialectic of resource and resistance has been known for many years, other connections are not as widely appreciated. For example, the Intergovernmental Panel on Climate Change (IPCC) and other authorities warn that climate change is very likely to bring with it more intense storms as well as more variability in rainfall. Thus, not only is misuse of power a source of disaster risk for some but "development" (defined as economic growth) may be implicated too.

Case Studies

Adopting the method of inquiring into root causes, dynamic pressures, and unsafe conditions, the previous points will be made concrete by examining urban and rural disasters in both the industrial West and one of the least developed countries of Africa.

Hurricane Katrina and Monsoon in Mumbai

Between August and September 2005, Hurricane Katrina triggered massive flooding in New Orleans, and more than 1,000 people died.

A month earlier, heavy monsoon rain had triggered widespread flooding in Mumbai, India's commercial capital, and in other parts of Maharashtra State, also killing more than 1,000 state-wide and 447 in Greater Mumbai. While the hazard events were both of high magnitude, many deaths could have been avoided, economic loss lessened, and the suffering caused during evacuation and sheltering could have been avoided were it not for a cascade of other processes.

Root Causes

There was long-standing social marginalization along race/caste lines, respectively, in New Orleans and Mumbai and also long-standing environmental degradation in the coastal wetlands (Katrina) and in the wetlands north of Mumbai and along the Mithi River.

Dynamic Pressures

These included rapid urbanization, urban budget pressure, and poor urban governance (leading especially to poor maintenance of levies and drainage in both cities).

Unsafe Conditions

These included the fact that low-lying residences were not raised on mounds or pillars in either urban region. Evacuation was difficult or impossible, especially since the most vulnerable population in New Orleans had no access to vehicles or public transportation. In Mumbai, the public transportation system was immobilized, there was little warning, and the sanitary conditions in shelters were poor.

Niger Famine

Niger is a large, landlocked country in the Sahel savanna zone of West Africa. Drought and a locust invasion were the natural hazard triggers of the 2005 food emergency in Niger that saw 12 million people in danger of starvation. However, this trigger alone would not have produced a disaster were it not for the following chain of events.

Root Causes

As in much of sub-Saharan Africa, there had been a long-standing marginalization of small

farmers because of urban bias in infrastructure and service provision and more recently a neoliberal policy making health care and education available only to those who can pay.

Dynamic Pressures

An economic policy promoted by international experts led to delays in food aid despite data produced by CARE and Doctors Without Borders documenting widespread malnutrition. Decision makers held to the belief that markets would respond. Other market-oriented policies included the selling off of the country's strategic grain reserve and allowing a small number of traders to corner the remaining supplies. The result was spiraling food prices. Irrigation systems were privatized also in accordance with International Monetary Fund recommendations. The small-scale farmers could not afford irrigation water, which could have provided a buffer during the drought.

Unsafe Conditions

Destitute farmers and pastoralists had no further assets to sell in order to feed their families. They were forced to reduce consumption, skip meals, and resort to wild foods ("famine foods").

Reducing Risks From Natural Hazards

Just as the past two decades have seen a move from a "hazard" to a "vulnerability" paradigm in the theoretical framing of disasters, so also the balance has shifted from reactive efforts in the face of natural hazards to proactive, preventive policies. Short-term warning and response, relief, and recovery activities remain vital to the protection of lives and assets. Warning, damage assessment, and settlement reconstruction are well established, but they are not without controversy. Evaluations of the experiences of Hurricane Mitch (1998), the Gujarat earthquake (2001), the Asian tsunami (2004), Hurricane Katrina (2005), drought and flooding in much of sub-Saharan Africa during the first decade of the 21st century, and the wildfires in Southern Europe and Australia (2008–2009) all show failure to learn lessons from failure. In addition, one can point to the following commonly recurring themes:

- Warning systems are still not people centered and culturally appropriate.
- Power relations and politics are often obscured and unacknowledged in what pass for “merely technical” exercises such as damage and needs assessment.
- Local economies still suffer, and dependency relations are still created by ill-conceived food aid assistance.
- Local knowledge and skill are often overlooked in the rush to “deliver” in postdisaster situations.
- Culturally inappropriate shelter and settlements are still built.
- Culturally inappropriate methods of psychosocial counseling are still practiced.

International Framework for Disaster Risk Reduction

The UN system with many other partners has attempted to learn these hard lessons and guide disaster reduction. Its vision is codified in the Hyogo Framework of Action (HFA), which calls for a global system of institutions working for disaster risk reduction from a local to an international scale. In this ideal schema, there is universal access to knowledge at all levels—clear lines of authority and decentralization that make funds and technology available at the optimal locations and scales. Awareness of hazards and vulnerability as well as recognition and use of capacities and skills are omnipresent at all scales. It is a beautiful vision, but like Plato’s *Republic*, the gulf between dream and reality is large. In fact, ample knowledge and effective tools exist. Funding, coordination, devolution, and decentralization are lacking and flawed. The pieces do not line up. A survey in 2009 by a network of 600 nongovernmental organizations working on disaster issues interviewed 7,000 local respondents in 48 countries—local government officials, civil society leaders, community representatives—and found that few national efforts documented by the UN over 4 years of investment in its HFA, had had an impact at the local level.

The British planner Peter Hall defined planning as the production of an ordered sequence of actions that lead to the realization of a goal. Attempts to integrate natural hazards and disaster

risk into planning complicate that simple-seeming definition. At the international scale, there is no guarantee that UN agencies and other international institutions do, in fact, share the same goal; despite efforts by the UN International Strategy for Disaster Reduction (UNISDR) to bring about diplomatic and rhetorical commitment to its HFA, implementation is uncertain. One may also question the “orderliness” of the sequence of actions given the voluntary and loose coordination among these international and national bodies. At the national scale, there are also divergent goals, and sequencing of actions is influenced by politics and privilege. For example, adoption of insurance instruments and use of financial planning tools such as insurance are not necessarily the result of a purely rational, technocratic exercise but one strongly influenced by political decisions and economic constraints.

Place, Locality, and Communication

It is often said that all disasters are local. This notion will be familiar to geographers as students of place and people-in-places. Although local government and local civil society organizations may be destroyed or at least put temporarily in a state of limited function when a disaster occurs, these forms of governance and self-help remain the core around which relief and recovery build. Also, the importance of such local institutions for prevention and preparedness is very clearly established. Yet many local jurisdictions are underfunded and poorly staffed. Civil society organizations may not have the confidence of local government, and mistrust may be mutual. This standoff is regrettable. While communities can and should do much to prepare and cope with situations themselves, social protection and protection of infrastructure are tasks that fall outside the ability of communities or even groups of communities united by civil society. The two sides—local government and civil society—need each other to achieve sustainable risk reduction.

Communication is a complex subject that features in much geographical research. As the blogosphere expands, and many new media develop and spread rapidly, communication is seldom unidirectional and only top down. During the 2004 hurricane season in the Caribbean, people

in the Dominican Republic received warnings of approaching storms by mobile phone from relatives living in Miami who had seen the television weather channel coverage. There is much horizontal and bottom-up news, analysis, and opinion expressed. These developments have complex consequences—transparency and accountability of authorities may be increased (and one recalls Nobel Laureate Amartya Sen’s aphorism that a famine had never occurred in a country with a free press). Yet this same technology can perpetuate myths and spread misinformation, potentially leading to repeats of the 1938 “War of the Worlds” scenario. Official warnings of tsunamis decades ago in the United States and New Zealand led people to go down to the shoreline to watch them. Informal tornado warnings sent by mobile phone text message to friends in 2009 led people to try to get a glimpse of the funnel cloud (the United States) while mobile phone cameras provided an incentive to wait in order to take photos (Canada).

Conclusion

Several main themes are central to an emerging consensus concerning natural hazards and the analysis of disaster risk:

- A complex systems framework is required to fully understand disaster risk and adequately inform policy and practice.
- This systems framework must include consideration of many subsystems, including politics, culture, economics, and social relations, as well as the dynamics of natural planetary and cislunar subsystems.
- Research and action (and reflection on action) is required at many scales from the 1:1 scale of local and daily life to that of the planet and its immediate surroundings over the long term.
- Crisis, emergency, disaster, and catastrophe (in an ascending scale of severity and social disruption) must be seen as continuous with “normal” and “routine” processes and practices, especially when marginal and deprived groups of people are exposed to potentially harmful natural processes and events.

NATURE

Geography is one of several academic subjects whose *raison d'être* is bound up with the topic of nature. Indeed, to explore the various ways in which geographers have approached this topic is, in effect, to examine the history and present constitution of geography as such. What is nature? Consult any dictionary and one quickly discovers that there is no straightforward answer. *Nature* refers to a wide range of things in a plurality of different ways. This is why it is an unusually complicated word; some say the most complex in the English language. The term has four principal meanings: first, the nonhuman world, especially those parts untouched or barely affected by humans; second, the entire physical world, including humans as biological entities and products of evolution; third, the power or force governing some or all living things; and fourth, the essential quality or property of something. Since the mid 19th century—the period when geography first became established as a teaching and research subject in the West—geographers have regarded nature (in one or more of its four meanings) as a central topic of inquiry. The question is why and how? In exploring the answer to this question, this entry provides major insight into why geography has changed so much over the past 150 years, and what its intellectual contributions have been relative to other subjects.

Beginnings: Geography and the Nature-Society Interface

Nature became central to geography's academic identity in two ways. First, scholars such as Halford Mackinder, Paul Vidal de la Blache, and Friedrich Ratzel, and William Morris Davis saw

the need to study nature as a whole rather than merely a set of discrete parts. Whereas subjects such as chemistry, physics, and botany focused on the investigation of select elements of the natural world, geography would study all these elements in combination (as Alexander von Humboldt had famously sought to do early in the 19th century). This view is what “physical geography” was, according to its 19th-century proponents such as Mary Somerville. In her 1849 book, *Physical Geography*, she defined it as a description of the Earth, the sea, and the air, the distribution of human beings, and the causes of their distribution. Second, this commitment to studying nature as an integrated, multifaceted system was accompanied by a desire to explore its two-way relationships with human societies. For Mackinder and the other early geographers, it was important that nature be studied in context, as something that forms the basis of and is affected by economic, cultural, and political practices. This investigation of “human-environment” relations could be conducted at a range of geographical scales, from the local to the global.

Clearly, geography had high ambitions in its fledgling years as a university subject; it was, in terms of subject matter and scope, very much a “world discipline.” Given this fact, all four meanings of the word *nature* were—unsurprisingly—bound up in geography's late-19th-century identity. The first meaning (the nonhuman world) was the domain of physical geography; the second meaning (the entire physical world, including humans) featured in attempts to explain why some societies seemed to be “closer to nature” than others; the third meaning (a supervening force or power) appeared in attempts to discover what one commentator, referring to physical geography, described as comprehensive principles rather than isolated facts; and the fourth meaning (the essence of something) was apparent in the widespread belief that geography could be a science like any other, its practitioners seekers after a singular truth possessed by all animate and inanimate entities.

Ideals and Actualities: A Growing Early-20th-Century Gap

Within a few decades, it became clear that geography's lofty ambitions were proving to be a burden for the early university geographers. By

identifying geography with a study of nature in all four of its meanings and in the two ways mentioned, geographers had arguably bitten off more than they could chew. The major problem was a practical one. Geography's perspective on the world was so comprehensive, and its subject matter so compendious, that it proved very difficult to demonstrate causal connections between the component parts of the nonhuman world, let alone all these parts and various societies worldwide. Some, like Mackinder, had hoped that a geographical equivalent of Charles Darwin's magisterial theory of evolution might be developed. But this hope was in vain. It was time-consuming enough to provide mere *descriptions* of these societies and their physical environs, never mind plausible explanations. As a result, most early research publications by geographers were beset by what—with hindsight—were serious intellectual weaknesses. For instance, monographs that focused on specific places or regions were often impressionistic and filled with unverified speculations about how and why nature and human society were as they were in given situations. At worst, this shaded into what we would now regard as racism. For instance, the U.S. geographers such as Ellen Semple and Ellsworth Huntington were apt to argue that certain physical environments produced human “races” less intellectually or physically capable than Europeans. Such beliefs were consistent with certain interpretations of Darwin's momentous discovery that all species are ultimately products of “natural selection”—even though Darwin himself was insistent that humanity was a single, indivisible species.

As a result, by the 1920s, gaps began to appear between the stated ideals of geography's founding figures and geography as practiced by their successors. On one side, physical geography began to fragment into subfields, which in turn focused more and more on biophysical phenomena as such (rather than their two-way relationships with human societies). For instance, the regional-scale study of landforms (geomorphology) was fairly well developed by the 1920s, and climatic geography was also becoming more sophisticated. On the other side, “human geography” began to take shape, with its emerging sub-branches usually lacking any deep grounding in physical geography. For instance, the economic geography

of George Chisholm in Britain and the political geography expounded by Isaiah Bowman in the United States were “systematic” rather than “synthetic” in nature. That is, they abstracted specific features of human practice (economics and politics, respectively) and focused on their spatial variation across Earth's surface. The biophysical basis of human activity was not ignored by either of the two geographers, but there was no pretense of offering a scientific and in-depth account of physical geography or of demonstrating its causal influence on human activity in a robust way.

These developments presaged a widespread turn to specialization and a fragmentation of academic geography that set in after World War II. The weakening of geography's holistic ambitions was no doubt aided by the increasing sophistication, precision, and rigor of other university subjects such as physics and economics, both of which produced notable theoretical breakthroughs by the 1930s, underpinned by mathematics and logic. Even so, geographers' commitment to study human-environment relationships at a range of scales did not entirely disappear. Instead, it was finessed and narrowed somewhat so that it could be delivered more readily. For instance, the American geographer Carl Sauer's influential 1925 publication *The Morphology of Landscape* argued that many ostensibly natural environments were the products of cultural practices, such that culture is the agent, the natural area is the medium, and the cultural landscape the result. This research agenda focused many geographers' attention on different cultures and the physical landscapes they created over time, licensing careful fieldwork and archival study. Sauerian cultural geographers needed to know some physical geography germane to their chosen cultural landscape, but the emphasis was on people's practices rather than biophysical processes or events.

Post-1945 Changes

World War II was a turning point for geography and its approach to the topic of nature. Many who subsequently gained positions in university geography departments served in the military between 1939 and 1945. The experience was formative for most, instilling a belief that precision, measurement, and rationality were virtues to which one

should aspire. At the same time, three other developments were significant. First, academic geography had failed to produce major books or intellectual innovations comparable with, say, John Maynard Keynes's (1936) *General Theory of Employment, Interest and Money*. This void became a cause for concern. Second, many outside geography had successfully argued that the physical sciences and the social sciences (with the humanities) had to be different by virtue of their subject matter. There could be no overarching theory or analysis of people and nature, it was argued, because the latter possessed ontological properties quite different from rocks, rivers, or ravines. For instance, humans are self-reflexive, linguistic, tool-making beings who can make their own history and geography. This argument drove a wedge between the two spheres—society and nature—that the original geographers had sought to bring together in a single intellectual frame. Finally, the embarrassment of “environmental determinism”—the prewar argument made by Semple, Huntington, and others that some human “races” were mere reflexes of climate and resources—made some geographers determined to “raise their game” intellectually.

After 1945, geography progressively splintered into two major halves (human and physical), with each fragmenting into relatively discrete “systematic” subdisciplines. The turn to specialization was undertaken in the hope that human and physical geography could become “spatial sciences.” They would discover—through careful measurement, hypothesis testing, and use of statistics—laws explaining spatial patterns (such as the common tendency of rivers to meander or migration flows to be inversely proportional to the size of destination cities). This necessitated a shift in the ways in which geographers tackled nature as a topic. First, interest in nature in the second sense of the term declined, and nature in the first, third, and last senses became the preserve of an increasingly subdivided physical geography. Second, human geography increasingly abstracted the study of political, economic, and cultural practices from their biophysical integument. The prewar fondness of some geographers for discussing “human nature” (in the biological sense) was also quickly abandoned. Third, physical geographers produced increasingly “scientific” descriptions, explanations, and even predictions of Earth

surface phenomena. Specialization, new databases, new remote sensing capabilities, and new computer technologies made this possible, but the price paid was intellectual disunity. Physical geographers divided nature into the five areas that constitute the field to this day (geomorphology, biogeography, climatology, hydrology, and quaternary environmental change). There was also a move toward small-scale, short-term studies because hypothesis testing was very difficult for macroscale analyses of (say) whole ecosystems or river basins. Finally, all the above meant that the study of human-environment relations became a minority pursuit, with “spatial analysis” and the search for general laws and theories becoming geography's new *modus operandi*.

These changes together bolstered the geographers' intellectual self-esteem and improved their external image within the world of higher learning. Ironically, though, geography was effectively abandoning the study of human-environment relations at the very moment when the title of William Thomas's (1956) famous book, *Man's Role in Changing the Face of the Earth*, was becoming as obvious as it was serious. C. P. Snow's famous complaint about the estrangement of “the two cultures”—one literary-humanistic and the other scientific-rational—was (ironically) applicable to postwar geography, the one subject that had made intellectual unity its *raison d'être*. Some efforts to maintain the “unity of geography” were made, with “systems theory” and “models” two of the suggested ways in which human and physical geographers might make common cause. But these efforts could not prevent a growing schism between human and physical geography, with nature effectively erased from the former's intellectual preoccupations. At the same time, physical geography's major branches extended into cognate subjects—such as ecology as in the case of biogeography. This made them increasingly interdisciplinary and reflected their inability to police their own turf once the idea of a unified physical geography was abandoned after 1945.

Recent Developments: The Rediscovery of Nature

Through the 1960s and 1970s, the situation as described above prevailed. However, from the

early 1980s, human-environment geography enjoyed a revival, but in a modern rather than traditional form. The revival was two-pronged. So-called political ecology grew into a major subfield, especially in American geography. Typically focused on rural localities and farming communities in the developing world, political ecology sought to describe and explain patterns of land use. It was, in part, a reaction to a minority tradition of “cultural ecology” in geography that had existed from the early 1950s. Cultural ecology investigated how preindustrial rural cultures were adapted to the possibilities and constraints of the immediate local environment—be it dryland or wetland, inland or maritime. Political ecologists pointed out that many late-20th-century rural communities in the developing world were being influenced by outside forces—notably, international trade and political decision making at the national level. This meant that local land use decisions were, increasingly, to be explained through a “chain of causality” extending up to the global level and often involving unequal relations of power and control. As a result, political ecologists downgraded the causal role of local ecology in explaining land use patterns in developing world settings. Today, political ecology—which now has both a “third world” and a “first world” strand—is a vibrant and large part of geography. In the United States, it has done much to add luster to geography’s reputation within the university system.

Coincident with political ecology’s rise to prominence, the geography of hazards and disasters also burgeoned as a subfield from the early 1980s. As the 20th century drew to a close, famines, floods, hurricanes, and other extreme natural events were claiming ever more lives. Why was this? A new generation of researchers set out to provide answers. Like political ecologists, many were influenced by new critical theories of society, and they argued that disasters may have natural triggers but their root causes lie in patterns of social inequality that make the poor vulnerable to hazard events. Again, this meant that hazards geographers typically did not inquire too deeply into the mechanics of volcanoes, landslides, or tsunamis.

For all their virtues, political ecology and hazards geography did not address the really big

environmental issues that came to people’s attention at the turn of the millennium. What is more, like Sauerian landscape geography, they proved far more adept at elucidating the human dimensions of the human-environment dialectic rather than the physical ones. Anthropogenic environmental change—or what is sometimes simply called “global warming”—calls for something very close to the holistic approach advocated by Mackinder and other like-minded geographers over a century ago. Looking ahead, the scale and complexity of global climate change demand connected multiscalar and multifactoral analysis and policy making. Having split into two subdivided halves (leaving only a modest “center”), geography is not well placed to rise to the challenge. However, some physical geographers are participating in new, transdisciplinary initiatives to understand the relations and feedbacks between the cryosphere, pedosphere, hydrosphere, and atmosphere. So-called Earth systems science and sustainability science have arisen in response to the intellectual challenge and practical threat posed by global environmental change. This is not leading to the reunification of physical geography, nor are physical geographers necessarily in the vanguard of either field. But the latter’s skills as field scientists, accustomed to dealing with open systems, complexity, and uncertainty, have proven valuable assets.

Meanwhile, what of human geography and the topic of nature? Since the early 1990s, human geographers have rediscovered nature after pretty much ignoring it for 30 years. This was not—as might be assumed—a response to global environmental change or a concern to understand and ameliorate “the human impact.” Instead, human geographers rediscovered nature in different ways and for different reasons. First, some radical economic geographers began to talk about the “production of nature” in late capitalist societies. This counterintuitive idea (“nature” seems precisely that which cannot be produced by humans) was intended to have two intellectual consequences. On one side, it called into question arguments about the supposed “end of nature,” voiced by environmentalists such as Bill McKibben (who, in 1989, published a well-known book of this name). Geographers such as Neil Smith argued that what we call “nature” has not been natural for a long

time and questioned the motives of those who would have us alter our way of life in the name of a supposedly vanishing nature in need of protection. On the other side, the production of nature argument directed geographers' attention to the actors and institutions that were consciously altering nature. Smith, a Marxist, suggested that capitalist firms—in their endless search for profits—were producing nature in ways that might not serve the public interest. This argument anticipated by many years the recent furor over genetically modified organisms cultivated for medicinal and nutritional purposes and developed by global agrofoods and pharmaceutical companies.

If Smith's work accented the profound biophysical effects of economic processes, other human geographers updated Sauer's arguments about the power of cultural beliefs. "New" cultural and rural geographers became deeply interested in the ways in which people's ideas, beliefs, and representations of reality become indistinguishable from the material world to which they refer. In a reversal of the epistemic realism that says that most human symbolic representations (words, images, music, etc.) are "mirrors" held up to the physical world, these geographers suggested that representations *become real* for those who hold them dear. For instance, in his 2002 book, *The Intemperate Rainforest*, Bruce Braun showed that Canadians descended from European settlers tended to see "nature" as a pristine space, a refuge devoid of any human presence. This contrasted with a native North American (First Nations) worldview in which what Westerners call "nature" is regarded as a living landscape inclusive of people. "Nature," Braun demonstrated, was a socially constructed idea, not simply an indisputable fact existing regardless of human beliefs about it. The question then becomes whose representation of "nature" comes to count the most in any given situation, why, and with what effects.

By the turn of the new millennium, human geographers such as Smith and Braun had succeeded in "denaturalizing nature." They weren't denying that what we call "nature" exists. Instead, they argued that the supposed "naturalness" of natural things was not all that it seemed to be. Their research revealed that if we want to understand "nature," we often need to look at who is talking about it or altering it, what their agendas

are, and why they use references to nature to communicate their own wishes and desires. However, arguments about the "production" and "construction" of nature attracted criticism from some human geographers. It was felt that these arguments rested on a conceptual dualism in which "society" called the shots over the domain of "nature." The material properties and agency of those things conventionally called "natural" seemed to recede from view. Sarah Whatmore, in her 2002 book *Hybrid Geographies*, argued that the dualism was unrealistic and diverted attention away from how entangled and messy the world actually is. She also argued that even in a world where humanity seemed to be "dominating" nature, nature possessed an enduring liveliness and a capacity to make a difference to the quality of human existence.

Whatmore's book is one example of a new "more than human" geography. Her project has found echoes in so-called nonrepresentational geography, which is especially prominent in Britain. The ambition has been to challenge the idea that the world is divided into two distinct ontological domains of "natural" and "nonnatural" (humanly made) things. Unlike those environmentalists and bioethicists who refer to nature's "special qualities" as part of a campaign to limit human "meddling," geographers such as Whatmore argue that the world comprises endless "hybrids." That is to say, they argue that life is a rich tapestry made up of entirely codependent, co-conditioning entities: rocks, machines, trees, textiles, animals, bacteria, and airplanes. There is, according to Whatmore, no such thing as either "society" or "nature." This amounts to a distinctive intellectual and moral argument: "Nature" is not disappearing or in need of "saving," nor will it exact a Gaia-like "revenge" on humanity, for the simple reason that nature—as such—does not exist!

Conclusion

More than a century after geography became a university discipline, we see that nature is still central to its identity and focus—but in ways that geography's founding figures could scarcely have anticipated. The holistic ambition to elucidate human-environment relationships long ago gave way to more limited attempts to investigate

biophysical processes, events, and entities. While physical geographers still regard nature as something existing “out there” amenable to “objective” understanding, we have seen that many contemporary human geographers have seen fit to question nature’s naturalness in a range of ways. Meanwhile, political ecologists and fellow travelers offer a contemporary and relatively contained version of what Mackinder had in mind in the late 19th century. If one adds all this up, a complex picture emerges: Contemporary geography’s contribution to understanding nature is diverse, even internally contradictory, but undeniably rich by virtue of this heterodoxy.

This fact notwithstanding, academic geography’s public image remains surprisingly close to that promoted by its founders. Unaware of the developments recounted above, many people believe that geography’s strength and distinctiveness lies in its ability to be both an environmental and a social science without problems or contradictions arising. Geographers themselves have done much to sustain this (partial) illusion. Many degree programs still emphasize “human-environment” interactions as a key theme—this is unsurprising, given that candid discussion of geographer’s far from unified approaches to the topic of nature would hardly make for good public relations! Continued calls for the “reunification of geography” made by a minority of academic geographers are unlikely to exert a centripetal force on such a centrifugal field.

NATURE-SOCIETY THEORY

Nature, it has been said many times, is a complex term that is both very familiar and extremely elusive. From “natural yogurt” to “human nature,” from “nature parks” to “natural boundaries,” the term has a range of uses so wide that a loss of grip on what it is we have in mind seems almost inevitable. Since geography framed itself as the discipline entrusted to study the relationship between humans and nature, the changes in our understanding of what nature is have profoundly affected what geographers study and how they study it. The prevalent Western geographical practices traditionally followed the modern dichotomy—presented as the commonsense understanding of the world—that separates nature from culture, or nature from society. In our everyday language, if something is social, then almost by definition it cannot be natural. And if something is described as natural, then it is unlikely to have much to do with society. Thus, despite a rich history of engaging with nature and the environment, geography started to interrogate nature in itself only in recent decades, having previously treated it reductively. Environmental determinism, possibilism, human ecology, and cultural ecology—as well as, to a certain extent, ecological anthropology—have thus been challenged or outright replaced by a multitude of intellectual newcomers. This entry explores many of these challenges, mentioning what new ways of thinking about nature and society have emerged, and how these have changed geographical practices. These include the social production of nature, the social construction of

nature or “social nature,” political ecology, as well as innovative approaches to materialities, heavily influenced by science studies.

None of these challenges emerged or exists in isolation, however much their proponents attempt to police the boundaries around them; instead, responses to these challenges have drawn productively and opportunistically from sources as wide as Marxist, feminist, poststructuralist, postmodernist, and postcolonial thought. Presenting these challenges as a succession of different schools or coherent approaches would be both artificial and stunted; instead, ideas have traveled, been challenged, rejected, and adopted by a variety of authors coming from different backgrounds. While some authors are easier to place within this spectrum, others resist fixity and draw creatively from a variety of more or less compatible new paradigms. Changes in the way nature and society are considered have not come from the social sciences alone; as many “new” ecologists and some political ecologists have highlighted, the understanding developed by ecologists and biologists that nature is not stagnant nor in equilibrium has also had a profound impact, changing how nature-society theories are made.

Nature as the Opposite of Society?

As noted at the outset, in everyday life in the Western world there remains a so-called commonsense understanding that the natural world and the social and political worlds are fundamentally different. Trees are trees, and politics—or society—is something quite different altogether. One challenge to this understanding has come from ecologists and, in particular, “deep” ecologists who attempted to collapse the binary by claiming that nature was all-embracing, making humans an (usually destructive) equal part of it. Paradoxically, this approach has done little more than reify the binary further: Nature, rather than being “everything,” ends up being considered only truly “out there,” surviving in the (few) remaining “real wild” places free from human impacts. This return to a romantic view of nature sees it as something pure and ideally untouched by humans that should be left alone to thrive through its own pristine devices. As the real remaining “true nature” is often physically located in the global South, these

approaches have frequently implied expelling the people who have inhabited these places for generations and directly took part in shaping them. This racism buttressed by naturalism ignores that places are peopled, have histories and geographies, and are social as well as natural places. In response to this, William Cronon first suggested that what might look natural to a Western eye is already mixed up with human worlds and that ignoring this directly threatens not only human livelihoods but the places themselves that proponents of such ideas seek to protect.

Such critiques drew heavily from social constructivism that emerged within the social sciences in the 1980s, and increasing attention was explicitly given to the social dimensions of nature. This change led geographers to explore how the construction of the spatial and the natural at the level of the social imaginary changed over time, for instance, when writing about protected areas and national parks. In such studies, discourses challenging the location and the (im)pertinence of the boundary between nature and culture were variously seen to question who and what were considered legitimate insiders and illegitimate outsiders. Nature, in this line of thinking, could no longer be simply “natural” or wild but rather was taken to be intrinsically social and political. Taking nature in itself, as nonsocial and unchanging, was seen to lead to the perpetuation of power and inequality in the wider world. In a series of works by geographers, drawing creatively from social constructivism, poststructuralism, and Marxism, an agenda emerged that studied the politicized construction of social natures. Binaries such as nature/culture, as well as wild/domestic and nature/artifice, were revisited in this light, all taken in a sense to be equally made and potentially equally political.

In other linguistic contexts, such debates about the construction of nature have taken place within other disciplines such as sociology, albeit with a slightly less political slant. Conceptions of nature and space have been seen to have wider and direct implications for the study of specialized difference as the (human) other is metaphorically and discursively constructed simultaneously to the (nonhuman or “natural”) other. Studies often focused on protected areas, since these particular spatial entities are directly designed for nature conservation, a topic frequently discussed and

appropriated by natural scientists. In this context, the temptations are manifold for those involved in the management of such areas for grounding what are in effect political decisions in “reason” or “objective science.” Grounded in natural arguments purporting to be value-free, linked to a conception of nature as wholly removed from society, such environmental discourses have a perverse tendency of taking on a life of their own, instrumentalized within reactionary politics that have a very real effect on people’s lives. Geographers have therefore put their finger on how political such discourses actually are, and how potentially disempowering they can become to less powerful actors and alternate forms of knowledge, including indigenous ways of knowing.

Putting the Political Back Into Ecology

This attention to livelihoods and social justice is particularly pronounced in what is often presented as the neighboring field of political ecology that has drawn additionally from cultural ecology and the political economy of development. Pertinent questions have included exploring how the relationship between society and nature has been defined and conceptualized, how access to land and resources is controlled in a variety of contexts, and how environmental costs and benefits are distributed. Understanding the interplay between power and space at multiple scales, symbolically and materially, has been a central concern of these approaches, drawing further from feminist and Marxist thinking.

Cindi Katz, for instance, while noting the common threads between the exploitation of people and the exploitation of nature, and referring to feminist and ecofeminist writing, has picked apart the notion of nature as an accumulation strategy, taken to be an investment for the future controlled by powerful capitalist interests. The environmentalist literature, she notes, is so full of the metaphors of investment, saving, and future gain that it often reads like boardroom script. All this, she argues, begs the question of who has rights to determine the appropriate use of preserved land, and how the altered temporalities and spatialities affect future access to the land. In parallel, geographers such as Jessica Budds, Michael Watts, or Paul Robbins have worked within similar

political ecology perspectives to explore examples as varied as the socio-environmental outcomes of water management in Chile, issues of drought and food security in West Africa, or the expansion of turfgrass in the United States. In the Chilean case, such an approach has illustrated how large-scale farmers have exerted greater control over water, while peasant farmers have been granted increasingly less access. Examination of social equity and the environmental aspects of resources management have highlighted new causes for concern in terms of social and spatial justice.

Rethinking the Divide Between Nature and Society

Literature from science studies and in particular from Bruno Latour and Donna Haraway provided a different and equally innovative impetus and theoretical grounding for rescripting the divide between nature and culture (or society), partly through a vigorous engagement with the process of scientific knowledge production. Scientific discourses, rather than being purely rational or objective, are taken to be vulnerable to critical scrutiny only by getting up close and tracing how it is made within the laborious assemblages of expert communities, particular words and phrases, documents, and professional protocols. For authors such as Sarah Whatmore and Steve Hinchliffe, these are seen to be performative achievements that are always partial, contestable, and incomplete. Knowledge producers are taken to be active participants who are situated, embodied, passionate, political, social, temporal, and spatial. They are spatialized, connected, and disconnected in varying ways to others and a lot of elsewheres. Their critique has focused on the silencing effect of approaches to the social construction of nature, noting how these have perversely assumed that that nonhuman world is mute and malleable, endlessly susceptible to being constructed following human ingenuity.

Diverse appeals to relations, actors, materiality, and material encounters have therefore led geographers to explore and spatialize concepts such as hybridity, exploring the physicality and co-presence of the nonhuman, both animate and inanimate. This exploration has led to approaches where nature, rather than being of interest only in

how it is imagined, represented, thought of, or conceived, is also explored through other concrete practices such as growing, gardening, infecting, digging, or counting. The dualism of nature and society is rejected as strongly as in other approaches mentioned earlier, but here this rejection is based on a detailed exploration of the networks—or assemblies or assemblages—that link together humans, organic nonhumans, technological objects, and quasi objects (or hybrid objects) that are combinations of technology and living organisms. Nature is not considered a malleable mass, passive and aspatial, susceptible to human will or to cultural, political, or economic forces and contestations, but instead, it is taken to be something that resists dynamically, takes part in its construction, and makes and shapes its multiple complex present.

Identifying what kinds of spaces remain for nature is crucial to this approach, assuming that it is neither dead nor neatly bounded in a self-sealed shell. This is a more directly political position than might at first appear, since it is driven by the idea that existing conceptions of nature lead to unjust politics that consign people, plants, and animals to unsatisfactory ends and limited spaces. By exploring the specifically messy assemblages as well as the physicality of bodies, plants, and animals that are mobilized to enshrine and construct particular spaces, more just policies are seen to be ultimately made possible. Rather than seeing nature fixed in particular places, figures of transgression—bodies transgressing accepting bounds—are used to foreground the mapping of ideology onto space. The overtly political claims of such approaches have been challenged by authors of a more Marxist bend, pointing out that such claims of politicizing practices that naturalize rarely address the thorny problem of power explicitly, leaving open the question of whether it is possible to weave this approach with practices of a nuanced, historically informed approach to power.

From Universal Nature to Global Nature

Nevertheless, this fusing of innovative ways of rethinking nature has led to a variety of material engagements with nature as something emerging globally. These approaches to the vitality of nature in part address the charge that the

nature-society theory has not contained enough ecology, or else has understood ecology poorly. In the most overt engagements with the dynamic relations and materiality of nature, it is taken to be always already unpredictable, vital, and always shot through with multiple, transversal, and non-linear relations. Interest extends to things as diverse as species, bacteria, viruses, and other runaway mobile hazards. Nature, on this global scale, is taken to be only the provisional outcome of local processes, the current state attained by a world of systems whose ultimate states can never be predicted. Having abandoned the certainties of the physical sciences, a material world remains, which is more deeply imbued with creative and self-generative properties than at any other stage of modernity. In arguing that such “global natures” are always specific assemblages whose intricate geographies form complex webs of different length, density, and duration, with varied consequences in different places, all experienced differently, Bruce Braun has dismissed all temptation of returning to the notion of nature as both singular—and thus culturally situated—or universal.

NEIGHBORHOOD

A neighborhood is a geographical entity located within a county, city, town, borough, or other local government political unit. Neighborhoods are not official political constructions, yet many have widely used popular names. For example, in Philadelphia, there is the “Northside,” “Southside,” and “Triangle” neighborhoods. The U.S. Bureau of the Census has tried to capture the neighborhood concept by creating census tracts, which are submunicipal areas of 1,500 to 8,000 people (typically about 4,000) that are considered relatively homogeneous with regard to demographic, housing, and economic characteristics. Census tracts have been created for almost every metropolitan area and for some nonmetropolitan areas. Local elected officials recognize the importance of neighborhoods, and hence many municipal governments have submetropolitan political districts called *wards*. Each ward has a neighborhood representative participating as part of the local governing body.

Governments cannot ignore neighborhoods because many people identify more closely with their neighborhood than with their local political jurisdiction. Homeowners typically have made their major financial investment in their home. Research shows a strong correlation between the rating of home quality and neighborhood quality. This association makes sense because the value of a home can be enhanced by an attractive, noise- and crime-free neighborhood, whereas a poor-quality neighborhood can depress home value. This entry reviews the qualities that residents perceive as determining the quality of their neighborhoods. It then discusses efforts—by government, by the residents themselves, and by nonprofit organizations—to maintain or improve neighborhood quality.

Neighborhood Quality

Most of what we know about U.S. neighborhood quality comes from the American Housing Survey (AHS), which collects approximately 50,000 samples from Americans about housing and neighborhood quality on average every other year from a sample of counties. The AHS shows that the vast

Mott Street in New York City, the traditional center of Chinatown, where the Chinatown Community Center is located

Source: Derek Jensen.

majority of Americans like their neighborhoods. Specifically, the author has combined early AHS surveys. (Neighborhood quality was measured as “excellent,” “good,” “fair,” and “poor” with later ones, which measured neighborhood quality on a 1 to 10 scale from “worst” to “best.”) Over the past 25 years, these surveys show that 30% to 35% of Americans rate their neighborhood quality as “excellent.” Another 46% to 52% rate their neighborhood as “good” quality. Neighborhood is a haven for nearly all these residents. The Pulitzer Prize-winning columnist Murray Kempton underscored that haven concept when he defined a neighborhood as a place where “when you go out of it, you get beat up.”

The remaining 15% to 18% rate their neighborhood as “fair” or “poor” quality. Yet averages are misleading. There are striking differences

among neighborhoods. In one neighborhood in Chester (Pennsylvania), 36% rated their neighborhood as fair quality and another 44% rated it as poor quality. The author identified more than half a dozen other U.S. neighborhoods where more than 70% of the respondents rated their neighborhoods as fair or poor quality.

There is nothing subtle about the causes of the different ratings. When residents do not identify even a single problem that bothers them, neighborhood quality will be rated excellent or good. When residents believe that a problem is so distressing that they want to leave, then their neighborhood is likely to be rated as fair or of poor quality. More specifically, perceptions of unsafe neighborhoods because of behavioral hazards (drug dealing, burglary, rape, and other criminal activities) and deteriorated physical

A Croatian neighborhood festival around the St. Jerome Croatian Roman Catholic Church in the Bridgeport neighborhood of Chicago. In the past, many Chicago neighborhoods were defined by the local parish. Although this is less true today, around some parishes there remains a strong sense of neighborhood and community that becomes very apparent during the summer festivals such as the one featured in these pictures. The tricolor red, white, and blue flag with the central crest is the Croatian flag.

Source: Eric Mathiasen.

conditions (blighted buildings, properties, infrastructure, and litter) lead to a poor-quality neighborhood rating. Based on thousands of samples in many neighborhoods, the author found that if both crime and blight were distressing problems, then more than two thirds of the respondents rated their neighborhood as poor quality. Also, crime and blight are typically found with other stressors, such as odors or

smoke from factories, incinerators, and other smokestack facilities; refineries and petroleum tank farms; airplane noise; and waste management facilities. In the most distressed neighborhoods, more than half of the population was bothered by more than 10 behavioral hazards and physical conditions.

The characteristics of a “better” or “worse” neighborhood are another important dimension of public reaction to neighborhoods. Nationally, about 43% of Americans rate their present neighborhood “about the same” as their prior neighborhood (this includes people who have never moved). Forty percent rate their current neighborhood as “better” and about 17% rate it as “worse.” In general, better versus worse is strongly predicted by the number of distressing problems. However, there are exceptions. For example, one woman in her late 30s rated her current neighborhood as better than her previous one, despite the fact that she lived across the street from a smelly and noisy petrochemical facility about which her neighbors bitterly complained. This woman, in contrast, indicated that this neighborhood was better than her previous neighborhood because it had no street gangs, and therefore, she believed that her teenage son would not become part of a gang and potentially get drawn into gang-related violence. In short, perceptions of neighborhood quality and neighborhood improvement ultimately are individual to each of us, although there are general patterns.

Findings about gender-related differences in neighborhood quality are intriguing. In general, women are more sensitive to hazards and neighborhood conditions than their male counterparts. There are good reasons for this observation, including women’s traditional roles as nurturers, women’s greater feeling of vulnerability, and that until quite recently women’s labor force participation rates were much lower than that of the men. Hence, it is not surprising that women are about twice as likely as men to rate their neighborhood poor quality. However, this difference is not found in the most distressed neighborhoods, places where on average six or more characteristics were labeled as distressing to residents. In these neighborhoods, the behavioral hazards and physical conditions are very apparent, and hence, men and women are equally concerned about them.

A final point about neighborhood quality is that neighborhood attractions such as good schools, convenience to public transportation, leisure activities, access to friends/relatives and to work, and neighborhood appearance have not been strong predictors of neighborhood quality rating. Those who rated their neighborhood as excellent rather than as good quality were more likely to point to attractive appearance and good schools. However, the relationship was not strongly predictive. In short, the major predictors of neighborhood quality are distressing behaviors and physical conditions.

Controlling Neighborhood Quality

The economic, social, and psychological importance that the vast majority of people attach to the quality of their neighborhoods cannot be understated. Accordingly, managing neighborhood quality has been the subject of considerable effort and public debate.

During the 1960s, when many inner-city neighborhoods were vandalized, burned, and partly abandoned, a neighborhood life cycle theory was born, which argued that neighborhoods pass through stages of life (birth, maturation, decline, death, and sometimes rebirth). Decline, it was asserted, is predictable and difficult, if not infeasible, to halt and reverse. For example, landlords will no longer continue to maintain aging properties, which then decline further. Lenders become unwilling to provide loans to people living in declining neighborhoods because they cannot realize an acceptable economic return. So-called redlining was a condition in which banks, insurers, and other financial institutions would not provide financial support to property owners in a neighborhood or part of a neighborhood. Continuing the cycle, middle-class people would leave, and the city government would withdraw police, fire, and sanitation resources, which exacerbated the deterioration. Some argued that the only option was slum clearance. The urban renewal programs of the 1950s and 1960s are testimony to the belief that some neighborhoods could not be salvaged and drastic action had to be taken. That redlining and other detrimental actions disproportionately have coincided with neighborhoods occupied by poor African Americans has

underscored the belief that racial transition means devastating neighborhood decline. Many retorted that this relationship is a self-fulfilling prophecy grounded in racism.

The fear of neighborhood decline has led to government, private, and individual efforts to maintain neighborhood quality. With regard to government, the federal, state, and local governments have tried dozens of financial and political tools. The federal government has provided funds for the police and for schools, pilot programs to stimulate the redevelopment of abandoned and underused brownfield sites, loans to neighborhood groups, and a host of other grant, rebate, and tax programs to try to halt decline and promote redevelopment. Each federal administration has tried to put its own brand on these programs, typically mirroring its political philosophy. For example, one of the major ideological clashes has been about place- and people-based programs. Some administrations (e.g., that of President Ronald Reagan) disproportionately focused on programs to assist people, including incentives to relocate, rather than on rebuilding neighborhoods. Others (e.g., that of President Lyndon Johnson) focused more attention on neighborhood programs. Many states have mirrored federal programs; some have developed their own ideas that have diffused up to the federal government and thence back to states and local governments.

Much of the power for maintaining and enhancing neighborhood quality rests with local governments. They can use zoning, building inspections, school construction and rehabilitation dollars, infrastructure improvements, financial incentives, tree plantings, and many other policy devices to improve declining and devastated neighborhoods. They can employ powerful eminent domain legal tools to take “blighted” property and build luxury housing (gentrification), commercial and community facilities, garages, and enlarged roads. The record of local government and their allies in state government, business, and labor organizations with regard to neighborhoods is mixed—ranging from major reinvestment to maintain the existing population and land uses to near-total destruction and building a new neighborhood for new people.

Because government and private business actions with regard to neighborhoods have been so controversial, groups have often created homeowner and neighborhood associations to protect their investments. Nelson estimates that the number of Americans living in neighborhoods with community associations rose from less than 1% in 1965 to 18% by 2004. These associations are expressions of collective self-regulation. Associations can mandate housing type, requirements on lawns and outdoor care, pets, and they can restrict who can live in a neighborhood and how they live in it; they can lay down a minimum age and minimum financial resources to acquire and maintain residents. Homeowners and neighborhood associations, cooperatives, and other private forms of governance have become a powerful tool to manage individual dwelling units and neighborhood quality. At the extreme, communities have literally been surrounded by the gates and fences; so-called gated communities have appeared in Sunbelt areas of Arizona, California, Florida, and Texas and other new suburban developments across the United States. One estimate is that there are more than 250,000 neighborhood associations in the United States. The typical one has about 200 housing units, but Sun City (Arizona) and Reston (Virginia) each have more than 10,000 units.

These neighborhood groups, in essence, are privatizing neighborhoods. With some exceptions, the local government is relieved of some expenses, such as security, fire, housing inspection, lawn maintenance, and trash collection. Politically, these associations demonstrate the power of homeownership and associated financial investors to manage neighborhood quality. Critics contend that they are antiprogressive mechanisms to control the access of poor people.

The third option for a neighborhood is to hope for one or a handful of strong-willed and talented residents or a not-for-profit organization, typically faith based, to organize and protect the neighborhood against crime, blight, developers, and sometimes even the government. The author has written about a number of these individuals: a woman who fought a losing battle against construction of an incinerator in her neighborhood; a resident who successfully sued the federal government, received funds, and then used those to turn her dilapidated public housing project into a

modest affordable housing facility; a city planner who insisted on high-quality housing standards; and a not-for-profit employee who fought for environmental justice in a rural community. These committed and talented people are rare, and relying on one or more of such persons to come along is a long shot.

NEOCOLONIALISM

Neocolonialism refers to the continuation of a colonial system in spite of formal recognition of independence of the formerly colonized nation. After World War II, when the European colonial system collapsed, the international community recognized the right to self-determination of peoples living under colonial rule. This right was

used to justify and promote the transition of former colonies to sovereign states, causing a rapid emergence of newly independent countries through the transfer of power from empire to nation-state. As a result, the total number of independent countries increased considerably from the late 1940s to the mid 1970s.

Despite their newly recognized sovereignty, however, these decolonized countries became subject to *de facto* control by Western powers, mostly by the same former empires that had once formally colonized them. Under this arrangement, the emerging countries were subjugated by indirect and subtle forms of domination by political, economic, social, military, and technological forces. In this context, neocolonialism differs from colonialism in the sense that colonialism is a formal and openly exercised system of domination of one country by another. Although neocolonialism is not a formal system, it continues as a practice in which Western powers retain economic but not formal control over the former colonies. Therefore, under neocolonial rule, the relations of power between the former colony and the former colonizer remained virtually intact.

Economically, the newly independent countries continued to be dependent on the Western powers. Facing development problems (i.e., unequal land distribution, inadequate infrastructure, insufficient capital investment, urbanization without industrialization, insufficient housing, and unskilled labor), many former colonies had to confront independence in detrimental conditions. In addition, the territorial integrity of many of those emerging countries was challenged by secessionist ethnic groups and the internal wars that resulted from the artificial boundaries inherited from their colonial times. All these conditions located most former colonies in a very disadvantageous position in the global economy. This disadvantageous position essentially relegated them to the status of producers and exporters of cheap raw materials as well as sources of cheap unskilled labor, while manufactured consumer goods were imported from the Western powers. This internationally imposed division of labor created the necessary conditions for the perpetuation of economic control and domination of the former colonies by Western powers even in the absence of

direct and formal political authority. As these conditions defined the economic situation of these emerging countries, unequal trade became another constitutive element of neocolonialism.

The *de facto* domination of the former colonies by Western powers did not rest solely on their economic muscle. Neocolonialism also restructured class relations by embracing, and sometimes creating, local elites who in return worked hand in hand with the Western powers. These alliances with local groups made the consolidation of neocolonial rule possible in these countries. As was the case under colonial rule, during neocolonialism the cooperation of small local elites with the Western powers had facilitated the West's ability to maintain a dominant position over the local population without any apparent direct involvement. In this way, foreign rule was disguised with a local face that legitimized the national independence and the sovereignty of the newly emerging countries.

To ensure their domination, neocolonial powers also resorted to other less apparent practices. These included aid and investment agreements offered to the newly emerging countries. These assistance packages, founded on promises of modernization meant to lead to social and economic development, have been used to secure the West's sphere of influence. Western foreign aid, therefore, often buys countries off to ensure their cooperation. Recipients of Western aid may be seen as collaborators when they fail to block or interfere with these neocolonial practices.

Likewise, debt became instrumental for neocolonial powers as it generated a new pattern for the extraction of economic surplus of the former colonies by the former colonizers. Debt peonage was characterized by capital outflows from the emerging countries to the Western powers exceeding the total of capital inflow into them. This placed the fragile economies of the former colonies at the mercy of their Western creditors and aid providers. Critics of these Western lending practices view the Bretton Woods institutions (i.e., the World Bank and International Monetary Fund, and, later, the World Trade Organization) as instrumental in creating this debt. These institutions enforce forms of capitalist discipline that most of the time have proved to be detrimental for the least developed countries. Consequently,

these emerging countries with fragile economies are forced to turn to the World Bank, the International Monetary Fund, and the World Trade Organization for help. This help comes through policies, loans, and grants that impose strict economic reforms that favor debt payment and neoliberalism (e.g., reductions in governmental spending in education, health care, and infrastructure; reduction of public assistance to low-income people; currency devaluations; and privatization of public goods). These structural adjustments imposed by the Bretton Woods institutions impose premature capital market liberalization in the former colonies, forcing these economies to succumb to the mighty economies of the West. This practice of forcing developing countries to eliminate trade barriers and compete with the industrialized West only leaves them with more debt—in a situation of interdependence (surplus value is extracted from poor countries to rich ones).

Along with the Bretton Woods institutions, multinational or transnational corporations (TNCs) are major agents underlying neocolonialism. These TNCs are rooted in the expansion of the colonial trading companies, and the vast majority of them have Western bases (three-fourths of all TNCs are based in North America, Western Europe, and Japan). However, the global rise of TNCs flourished during the post-World War II economy and in the context of the new international division of labor (the internationalization of production and the spread of industrialization) that was widely imposed during the 1960s. Currently, through direct ownership of the different parts of the production processes and also through subcontracting and other indirect influences, TNCs account for an increasing proportion of the world's flow of trade, investment, knowledge, skills, and technology transfers. Several have higher turnover than the majority of the world's countries, and they employ millions of people worldwide. TNCs largely operate in the developing world, where they have virtually unlimited access to cheap labor and cheap raw materials, and because of their vast capital and influences over trade, investments, technology transfers, and employment, they have the ability to stabilize and/or destabilize entire national economies. Therefore, their presence in

the developing world has mixed outcomes. On the one hand, TNCs can create jobs, promote technology transfers, bring foreign exchange, increase the median income, and invest in education and health care. On the other hand, TNCs can also cause the displacement of local suppliers, the lowering of national tax regimes, and the softening of labor markets and environmental laws in the developing world. In addition, the profits and the surplus capital generated by these enterprises are repatriated to their countries of origin (mostly in the West), doing very little to ease the debt situation and solve the financial problems of developing countries. This economic power that TNCs have over developing countries represents another form of neocolonial domination. Moreover, TNCs have a long history of political involvement and interference in the developing world. Their interventions range from demands for better incentives (e.g., tax relief and soft environmental laws) to support for military incursions and covert or indirect operations. States in the developing world that confronted multinational corporations often have faced military coups d'état and/or covert operations carried out by the military and intelligence agencies of the Western powers (e.g., Iran in 1953, Guatemala in 1954, Indonesia in 1965, Chile in 1973, Ecuador in 1981, Panamá in 1981, and Venezuela in 2002).

The United States, along with Western European countries, have played a central role in the development of neocolonialism. Following the Spanish-American War of 1898, the United States joined the Western European countries as a colonial power. First through colonies and later through unincorporated territories (e.g., American Samoa, Guam, Northern Mariana Islands, U.S. Virgin Islands, Puerto Rico), the United States expanded its dominions over foreign lands. From the perspective of neocolonial theory, the enormous size of the U.S. economy and military and the influence of American culture and politics worldwide has made the United States a paradigm of neocolonialism. After World War II, the United States emerged as the absolute military and economic superpower. This position was reflected worldwide through its political and economic influences, as well as through its military muscle. Likewise, the superpower position of the United States was reinforced through the

influences of the American popular culture and media. In other words, the superpower condition of the United States explains why, regardless of the fact that the United States represents less than 5% of the world's population, it consumes more than 25% of the world's resources and its influences reach virtually the entire surface of the earth. Such colossal accomplishments were made possible through the neocolonial rule imposed over the developing world.

In the current period, the structures of power operate less through military or direct political control than through economic influences. Shaping the global economic conditions has become increasingly crucial to the assertion of global domination. Now, it is trade rather than conquest that determines international control. Thus, neocolonialism can be seen as a new form of colonialism in which de facto economic domination fails to respect the independence and sovereignty of many countries and thus perpetuates the inequality between developed and undeveloped countries.

Neocolonial theory holds that the West's de facto domination over much of the developing world has obstructed the economic growth and development of these emerging countries. The former colonies are virtually powerless; thus, there is little they can do to escape this system of neocolonial control. The world economy is dominated by Western powers and, therefore, is fixed to their interests. Consequently, the rules of neocolonialism work against the undeveloped countries, which have relatively little experience in industrialization, have to face an imposed international division of labor, and are forced to compete in a system of unequal exchange. These conditions only favor the Western powers, perpetuating neocolonialism.

NEOGEOGRAPHY

The term *neogeography* relates to technical developments in Web-mapping technology and spatial data infrastructures that have significantly changed how users collect, share, and interact with geographic information online. These changes can usefully be considered as a component of broader changes in the nongeographic Internet referred to as Web 2.0. Goodchild maintains that

the early Web was primarily one-directional, allowing a large number of users to view the contents of a comparatively small number of sites, [whereas] the new Web 2.0 is a bi-directional collaboration in which users are able to interact with and provide information to central sites, and to see that information collated and made available to others. (2007b, p. 27)

Neogeography can be considered as the geographic implementation of this principle and is about both technological innovations and the new modes of interaction that these changes enable.

The two main technologies that have driven both neogeography and the Web 2.0 paradigms are Asynchronous Javascript And XML (AJAX) and Application Programming Interfaces (API). AJAX enables the development of Web sites that have a look and feel more akin to a desktop application and have improved the usability of

Web mapping significantly by enabling direct manipulation of map data where user interactions (e.g., click and drag) are visualized instantaneously. This new type of Web site application compares favorably with traditional Web Geographical Information Systems (GIS), where users typically click a pan or zoom control and then wait for the page to reload before visualizing the result of the interaction. The XML component of AJAX refers to eXtensible Markup Language, which is a set of data standards that enable information to be formatted in such a way that it is usable across a variety of different software. For example, using GeoRSS (an emerging XML-type standard), location can be coded into online content, such as news feeds or blog posts. This information could then be used in multiple Web applications; for example, simple display on top of a base map in a Web browser or the listing of content, which is attributed to locations “near” a user of a GPS- and Internet-equipped mobile handset. In both applications, the source information would remain the same; however, the application would differ. API are available from a variety of Web sites, both spatial (e.g., Google Maps, Yahoo! Maps, or Microsoft Live Maps) and aspatial (e.g., Flickr, Facebook, Nestoria) and provide a series of functionality to third-party applications. For example, the API of Google Maps provides basic GIS operations, such as the ability to draw shapes, place points, geocode locations, and display these on top of high-resolution base map or satellite data. An example of the Google Maps API would be the Web site www.londonprofiler.org, which displays a variety of high-resolution sociodemographic data about London on top of the Google-supplied base map and satellite data. Although it is still a technical task to create Web sites using API, the construction of these applications is far simpler than the learning curve required to install, manage, and configure more traditional Web GIS platforms.

The technologies of Web 2.0 have created new ways in which users can create, share, and use information. Often referred to as “crowd sourcing,” this concept relates to how large groups of people can work together toward some common goal by performing functions that are either difficult to automate or expensive to implement in a nondistributed environment.

Within a neogeography context, Daniel Sui calls these changes the “wikification of GIS,” borrowing the terminology from Wikipedia, the user-generated online encyclopedia. A successful project using a collaborative paradigm (wiki) is OpenStreetMap (www.openstreetmap.org), which aims to create a set of free-to-use global map data through assimilation of volunteered geographic information in the form of user-collected GPS tracks and digitized satellite photographs.

Although the use of the term *neogeography* may lose popularity in a similar way to other online neologisms such as “cyberspace” or the “information super highway,” the underlying principles of collaboration and openness are unlikely to lose momentum, and fit into a broader movement toward pervasive GIS. Neogeography has made basic GIS operations and data increasingly accessible to the masses, enabling users with no previous geographic training to create, search, and share their own geographically referenced information. However, the implications of this increased visibility and availability of GIS have ethical implications that need to be considered. These tensions are illustrated between the public interest in high-resolution geographic data and the converse right to privacy. A recent example of these tensions was illustrated by the release of the Google Street View service that supplies horizontal and vertical panoramic photographs of numerous metropolitan areas around the world. Privacy concerns were raised over the incidental capture of individuals and cars within these images, and Google has now responded by automatically blurring faces and car number plates. This type of corporate responsibility should be perceived positively and illustrates how technology can be used to limit potential ethical concerns of innovative new data sources. A major contribution of neogeography has been to break GIS away from the realm of the isolated desktop user and in doing so has created a broader and enthusiastic new audience who may traditionally have only engaged with geographic information in simple map-reading tasks.

NEOLIBERAL ENVIRONMENTAL POLICY

Neoliberal environmental policy comprises a critical component of contemporary nature-society interactions. Neoliberalism is most simply defined as a political philosophy that promotes a greater reliance on markets and less reliance on government for the provision of nearly all goods and services, including environmental services. Invoked by powerful multinational institutions and many national governments to justify their approaches to trade and investment, it has fundamentally shaped the evolution of international governance, development, and environmental regulation over the past 25 years or so. Environmental aspects of neoliberalism include not only explicit, direct policies, such as those creating new environmental markets through privatization schemes of various kinds, but also the indirect environmental effects of market liberalization.

Goals and Tools of Neoliberal Environmental Policy

For its proponents, neoliberal environmental policy reflects commonsense economic science that

produces growing, market-oriented, profit-driven economies that will soon generate sufficient jobs and taxes to rectify any social or environmental problems that might occur. Neoliberal environmental policies contrast with those of previous import-substitution and Keynesian periods, when “command-and-control” approaches sought to solve environmental degradation problems through regulations, standards, fines, and lawsuits that force producers to reduce their environmental impacts. Neoliberal economists criticize that approach as inefficient, unnecessarily expensive, inflexible, and stifling of innovation. A better approach, they argue, comes from private property arrangements and markets that internalize the costs of environmental degradation, and so they promote privatization of agricultural land, fisheries, pollution sinks, biodiversity, and public enterprises ranging from mining companies to water provisioning systems.

Many other neoliberal policies, such as free trade, also affect the environment. Although the environment gets little explicit consideration in the theory promoting, for example, an end to import quotas and tariffs, the general idea is that increased trade increases wealth, which eventually leads to environmental improvement. Similarly, neoliberalism promotes decreased state expenditures, decentralization, and the participation of civil society in governance. Reconfiguring environmental governance to include streamlined states, civil society actors, and local, presumably more representative, levels of government is thought to bring greater efficiencies to environmental regulation.

Criticisms of Neoliberal Environmental Policy

Opponents contend that free trade and investment rules create a global “race to the bottom” as companies look for the regions with the lowest effective environmental regulations. Under neoliberalism, debt payments and foreign exchange earnings become key goals of governments. Natural-resource-dependent sectors such as agriculture, forestry, mining, and fishing often provide the required exports, almost always with high environmental impacts. Meanwhile, other neoliberal policies increase income disparity

and poverty, which drive cycles of environmental degradation as the poor erode soils and clear forests in their desperate attempts to make a living.

Critics of environmental privatization point out the extreme difficulty in constructing resource-conserving markets, especially because markets almost always give too low a value to environmental attributes. They also raise several human rights concerns: First, all people have the right to clean water and air; second, forests, fisheries, and biodiversity have many users and possessors who are harmed when property rights are taken away from them; and third, many environmental attributes and livelihood resources have values that have no price and cannot be justly exchanged for money in markets.

Critics on the left see neoliberalism as a false justification for the plunder and despoiling of natural resources at the hands of transnational corporations, aided and abetted by institutions such as the International Monetary Fund (IMF), the World Bank, and the World Trade Organization (WTO), in collusion with the local political networks. Justifying their actions with selective and hypocritical applications of neoliberal ideas, these U.S.-dominated organizations impose weak environmental and labor regulations and preferential tax and investment regimes. Such conditions allow companies to use destructive inputs and processes banned or severely restricted in developed countries. Similarly, critics on the left argue that privatization is a form of enclosure, essentially transferring wealth away from large numbers of mostly poor people to a small number of powerful actors. *Biopiracy*, for example, is the term they would apply to private companies' search for and patenting of potentially profitable genetic resources originally found in environments owned by specific groups or by humanity in common.

Market Liberalization

Neoliberal policymakers promote market liberalization—the freeing of markets from government intervention—mainly through structural adjustment programs and free trade agreements. Both have controversial environmental impacts.

Structural adjustment programs (SAPs) were imposed on indebted countries by the IMF as a condition for debt renegotiation. They typically

involve currency devaluations, the reduction of public spending, price reforms, subsidy reductions, privatization of public enterprises, and decreased or eliminated export taxes. Such policies make natural resource exports cheaper on world markets and attract foreign investment, while diminishing the ability of the state to regulate environmental impacts. Free trade agreements also have the goal of increasing international trade through decreased tariffs, export taxes, and import quotas while providing protections to investors and owners of intellectual property. Following market liberalization, mining, fisheries, logging, and the area devoted to export crops typically increase.

Critics argue that these instruments of market liberalization create unchecked growth and pollution. They promote a so-called race to the bottom, making it too easy for companies to avoid responsibility for their environmental degradation and harming people who depend on natural resources, such as small farmers, fishers, forest people, and those living downstream from mines. Furthermore, they increase poverty and inequality, which also has negative environmental implications.

Trade negotiations often represent business interests only, but social movements increasingly resist them or call for renegotiation. Such movements criticize the role of trade agreements in undermining national environmental regulations. WTO rules, for example, require that tuna fish caught in nets that also capture dolphins must be treated the same way as tuna caught by dolphin-safe methods; countries cannot simply ban the import of tuna captured by methods that harm dolphin. (They may, however, allow dolphin-safe labeling programs leaving it up to consumers to choose.) Provisions in some free trade agreements give investors the right to sue for compensation if environmental regulations reduce the value of their investments. For example, a U.S. company used North American Free Trade Agreement (NAFTA) provisions to successfully sue a Mexican local government for refusing to permit a hazardous waste landfill.

On the other hand, free traders would argue that trade creates efficiencies that have environmental benefits and provide incentives to conserve productive resources. Furthermore, they claim

that many environmental regulations distort trade and protect domestic producers who don't deserve it. In addition, increased foreign investment is associated with cleaner production processes than local industries due to compliance with international standards, corporate requirements, fear of lawsuits, and the use of more modern and efficient technologies. Finally, any increased poverty is a short-term impact. In the long term, market liberalization raises incomes and permits increased investment in environmental conservation.

The agricultural implications of market liberalization are particularly important for the environment. Market liberalization promotes export agriculture where it is viable but inhibits trade protections for struggling agricultural sectors and regions. Despite many years of negotiations, international trade agreements have been unable to significantly decrease the agricultural subsidies and import protections that the United States, Europe, and Japan lavish on their domestic producers, but they have been successful in getting developing countries to open their economies to agricultural imports. This creates rural crisis in many regions of the world where small local producers are unable to compete with modern, heavily subsidized producers. In marginal agricultural areas, immigration increases, brush and trees revegetate abandoned agricultural fields in a kind of forest transition, rural landscapes are transformed, and traditional crop varieties risk becoming extinct.

New Environmental Markets

Neoliberal ideas hold that the environment is best managed when resource rights are well-defined, defensible, and exchangeable. This can be attained through the privatization of water provisioning systems, public enterprises, and state-owned or common property lands. Even hard-to-divide resources can be privatized and brought into markets through the allocation of tradable sulfur dioxide and nitrogen oxide pollution allowances, carbon credits, transferable fishing quotas, and payments for environmental services. Even something as amorphous as biodiversity should be brought into markets through payments for its conservation and patents on genes and genetically modified organisms with profit potential.

The privatization and decentralization of water management has sparked virulent antiglobalization protest in some cases, such as in Cochabamba, Bolivia, but privatization operates with little public concern in many other places, including parts of the United States, Europe, Australia, Chile, and South Africa. Market purists believe that even water should be privately owned and tradable on a free market with all users paying for provision and treatment. They promote the participation of large international profit-seeking water companies to invest in and manage water systems all over the world. Opponents of the idea assert that water is a basic need that all people deserve, regardless of ability to pay. Case studies of neoliberal reforms in water indicate extreme difficulty in assigning rights transparently and unequivocally, setting effective transfer and use rules that provide market incentives for conservation and efficiency, and frequent conflict with previous approaches to the use and distribution of water. Critics raise serious concerns that market approaches fail to recognize the value of water in the environment, such as for wetlands and other habitat, a failing also shared by public provisioning systems.

Privatization and marketization are also promoted to protect the environmental services provided by forests and watersheds, including water capture and filtration, biodiversity conservation, and carbon mitigation. An international global warming treaty, payments for hydrological service programs, and similar projects create possibilities for some of those services to generate income streams for rural land managers, unleashing market incentives for land use practices that enhance the targeted environmental service. Critics of the idea identify substantial problems monitoring and placing values on such services. They identify the challenges of protection in areas where no one is willing to pay for services, such as water provision and carbon mitigation, and question the economic sustainability of many existing schemes once the initial subsidies from taxes, international development, and the government disappear. Furthermore, like many other market-based approaches, they question the equity implications of such instruments because they favor large producers with economies of scale and buyers with the greatest purchasing power.

Nongovernmental environmental certification systems, of which organic certification is the most familiar, constitute another form of environmental market congruent with neoliberal environmental policy. These programs rely on a set of standards according to which production processes in specific places are evaluated by third-party auditors so that the environmental qualities of products can be identified with a label. Since these programs are voluntary and nongovernmental, they don't violate free trade treaties. Thus, they constitute important new forms of neoliberal environmental governance that generate transnational scales of interactions between social movements, nongovernmental organizations, and private sector stakeholders.

Varied Outcomes and Social Responses

Under neoliberalism, environmental governance is reorganized, often scaled upward to transnational institutions of various kinds. This also restructures environmental politics. Social movements that previously might have made demands on governments to impose regulations on markets now shift their attention to other actors. Some might dress up as turtles to protest WTO rulings limiting national ability to call for turtle-protecting devices on international shrimping fleets. Similarly, ethical trading companies, activists, certification systems, and consultants displace the politics of environmental regulation to distant sites of production, to multistakeholder organizations, to media outlets, and to consumers' shopping carts.

Specific outcomes of neoliberal environmental policy vary greatly, depending on local conditions, histories, and social responses. Neoliberal forestry policies, for example, generally promote privatization and exports, especially through plantations. The emphasis on secure property rights as the foundation of markets, however, can support the formalization of common property rights to indigenous territories, and thus, community forestry can be compatible with neoliberal ideas and policies. Researchers warn against invoking neoliberalism as a monolithic construct with the same outcomes everywhere.

NEOLIBERALISM

A set of philosophies and discourses emphasizing the importance of free markets to development and prosperity, neoliberalism emerged as the guiding rationale for a wide range of responses to declining levels of economic growth in the 1980s and 1990s. A term used largely by its critics, *neoliberal philosophies* combine elements of classical liberalism with those of social conservatism. This entry reviews the central concepts of neoliberalism and its evolution in the global North and South; examines the neoliberal perspective on relationships between the state, markets, and civil society more generally; and describes criticisms that have been directed at neoliberalism, particularly with respect to its impact on the poor.

The Development of Neoliberalism

Greatly influenced by the writings of the neo-classical economist Friedrich Hayek and, later, Milton Friedman, proponents of neoliberalism view the minimally regulated market as the

institution best able to maximize economic growth and the creation of wealth. For many neoliberals, economies where the forces of demand and supply determine how and where goods and services are produced and exchanged are not only more efficient in generating and allocating resources than the state but also morally superior, because they give individuals freedom to choose the goods and services they want to consume. Although the central importance of free markets to the efficient and equitable allocation of resources is a shared feature of all neoliberal discourses, geographers agree that there is no pure definition of neoliberalism. This is because there are not only significant differences in the range of practices that scholars associate with neoliberalism but also different degrees of market engagement that countries have employed in different geographical contexts.

Friedrich Hayek

Hayek saw free markets as vital to individual liberty because free markets ensured that individuals could not manipulate the resources of a given environment for their own advantage. By communicating information in environments of uncertainty, markets, Hayek argued, facilitate a harmonious order where no individual is able to amass all the complex information required to manipulate the world to his or her own advantage. Writing in 1944 on the relationship between collective forms of social and economic organization and tyranny, Hayek viewed economies that relied on markets to allocate resources as more democratic than those where the distribution of resources was determined by states. In his famous book *The Road to Serfdom*, Hayek argued that centrally planned economies, such as the Soviet Union and Nazi Germany, were more likely to resort to coercive restrictions on individual freedom than capitalist economies because they relied on states rather than markets to determine how resources were allocated. He believed that the impossibility of amassing all the information needed to efficiently and fairly distribute resources inevitably led states to use coercive means to achieve economic control. For Hayek, state intervention in the allocation of resources in an economy was deeply problematic. Hayek argued,

“Economic control is not merely control of a sector of human life which can be separated from the rest . . . it is the control of the means for all our ends” (1944, pp. 91–92).

Milton Friedman

Hayek’s ideas on the relationship between economic and individual freedom were further developed during the 1950s and 1960s by Milton Friedman, who challenged the macroeconomic demand management approach to economic stability advocated by John Maynard Keynes, which was influential in the responses of Britain and the United States to the 1930s Great Depression. A member of Hayek’s Mont Pèlerin Society, founded in 1947 to preserve the fundamental economic principles of classical liberalism, Friedman argued that economies were best stabilized through controls over the supply of money rather than through state fiscal intervention, which he argued tended to produce inflation. Like Hayek, Friedman viewed economic interventions by states as impediments to economic growth and individual liberty. In his 1962 book *Capitalism and Freedom*, he advocated a range of policies to curb forms of state regulation such as military conscription, the levying of income tax, and the fixing of exchange rates. While the ideas of Hayek, Friedman, and other supporters of laissez-faire capitalism gained little popular support during the 1950s and 1960s, they were revived during the 1970s and 1980s when the stable and continuous patterns of economic growth associated with the Keynesian demand management approach ceased to be successful. It is during this period that the philosophies underlying neoliberalism evolved into a loosely coherent set of economic strategies, adopted by regions in both the global North and the global South.

Neoliberalism in the Global North

In the global North, neoliberal philosophies became increasingly popular as the Fordist system of production and consumption, which had developed in tandem with the Keynesian welfare-oriented approach, ceased to produce stable rates of economic growth. Fordism emerged across North America and Europe as a successful regime

of accumulation because it balanced the mass production of standardized industrial goods with high levels of state-supported mass consumption. Between the 1940s and 1960s, Fordist industries became engines of economic growth because they achieved high levels of productivity through the use of technologies that allowed firms to maintain strict control over the production process. As a result, Fordist mass-produced goods were low in cost and affordable to large segments of most population. Fordist mass consumption, on the other hand, was facilitated by states through policies that supported the family wage, job security, and welfare-oriented investments in areas such as health and education. The stable economic growth produced under Fordism began to break down as early as the late 1960s, as industries in a number of sectors became increasingly less profitable. By the mid 1970s, rising levels of unemployment and inflation signaled the end of Fordism and the Keynesian social contract. The crisis of the 1970s created the context for the revival of the ideas of Hayek and the policy prescriptions of Friedman, which heretofore had been largely ignored.

Neoliberalism in the Global South

In the global South, neoliberal discourses emerged in the wake of the 1974 oil price crisis and the rising levels of debt that followed increases in interest rates in the United States. Particularly, among Latin American and Caribbean countries that had borrowed international capital to finance state-led import substitution strategies, the oil price shocks, spiraling debt, and the ensuing recession in the global North challenged the role that states would play in the process of development in the future. In Chile, for example, the 1973 coup d'état that overthrew the democratically elected socialist government of President Salvador Allende marked the beginning of a new relationship between states, markets, and civil society. Under the leadership of General Augusto Pinochet, Chile became the first country where neoliberal policy prescriptions were systematically implemented. Closely influenced by the views of Milton Friedman, whose former students became key architects in the neoliberal restructuring of Chile, these policies included the reduction of public welfare spending, the dismantling of

regulations over entry and competition in markets, and the privatization of formerly nationally owned industries. Described by Friedman as shock treatment, the sudden removal of price and currency controls, the withdrawal of state subsidies, and the liberalization of trade were designed to deliver a quick jolt to the economy that would restore market fundamentals and stimulate growth.

Shock therapy in Chile laid the foundations for a more systematic set of neoliberal strategies that became known as *structural adjustment programs* (SAPs). Administered by the International Monetary Fund (IMF) and the World Bank, and influenced by the U.S. Treasury Department, SAPs aimed to reduce government fiscal imbalances and debt by opening up economies to the market through privatizations, devaluations, reductions in public social spending, and the lifting of trade restrictions and state controls over prices. States seeking financial assistance from either of these institutions were obliged to implement these policies as a condition of gaining access to loans. By the 1990s, nearly every country in the global South had entered an SAP and had begun to implement the relatively standard package of stabilization, privatization, and liberalization policies. Collectively, these policies also became known as the *Washington Consensus* in recognition of the degree of influence that the political and technocratic institutions of the U.S. government had over their formulation.

Changing Relationships Among States, Markets, and Civil Society

The importance of the United States in shaping the nature of neoliberalism in the global South during the 1980s is a reflection of the changing relationship between states, markets, and civil society that had begun to be put into practice by Margaret Thatcher, the then prime minister of the United Kingdom, and Ronald Reagan, the then president of the United States. Both leaders were social conservatives who supported the ideologies associated with classical liberalism that stressed the importance of individual private property, free markets, limited government, and the rule of law. Deeply influenced by the work of Hayek, Thatcher felt that the solution to the

economic crisis of the 1970s lay in the restoration of the market as the key institution responsible for the allocation of resources. But to make the free market play a more central role in everyday life, policies needed to be put in place to reduce the role played by the state in the provision of welfare and increase opportunities for the private accumulation of wealth. The early policies introduced by Thatcher and Reagan revolved around the relaxation, and in many cases, removal of market regulations, such as fixed exchange rates; the reestablishment of private property rights, largely through the privatization of previously nationally owned industries; and the retreat of state from the provision of social welfare. Important to both leaders was the need to make labor more responsive to the changing dynamics of capital, and this was achieved by breaking the old Keynesian social contract by weakening the power of the labor unions and reducing the state's obligation to provide welfare support for all its citizens. In the United States, for example, many of the rights-based income support programs that formed part of the New Deal were restructured in ways that increasingly required beneficiaries to participate in work or educational programs as a condition of receiving aid. As geographers such as Jamie Peck observed, the shift from welfare to workfare has been part of a new system of labor regulation that ensured that workers continued to work even in environments where real wages were declining and employment was becoming more casualized, that is, stripped of many of its benefits, including job security. Throughout the 1980s and 1990s, other governments in the global North implemented similar neoliberal strategies, each with its particular institutionally mediated market-enabling foci.

More than a narrow set of philosophies aimed at economic reform, neoliberalism has also redefined the social relationship between states and civil society. Feminist scholars argue that many of the social policies that have accompanied neoliberalism have sought to create a new type of citizen, one who is self-sufficient, entrepreneurial, and able to compete in markets, without minimal reliance on collective resources. Often drawing on social conservative discourses that valorize individual responsibility and traditional values, neoliberalizing states in both the global North

and the global South have tended to reward and punish particular groups according to the degree to which they meet the neoliberal citizenship ideal. For example, many neoliberalizing states encourage individuals to become more entrepreneurial by promoting microcredit programs that offer small loans at commercial interest rates to those with no incomes. Conversely, to discourage individuals from relying on collective forms of welfare, many have instituted programs such as workfare, which take away the right of individuals to determine the conditions under which they will provide their labor.

Criticisms of Neoliberalism

Critics of neoliberalism view the policies and practices that have been used to reorient and more closely integrate economies within increasingly global markets as deeply unequal and unjust. David Harvey argues that the policies associated with neoliberalism heighten patterns of uneven development because they promote forms of capital accumulation that enable the richest class groupings to accumulate surpluses by appropriating the assets and rights of others. He defines the type of capitalist growth associated with neoliberalism as "accumulation by dispossession" to highlight the extent to which these policies have redistributed wealth from the poorest to the wealthiest of people and places. Many grassroots civil society groups oppose neoliberal policies because of the adverse effects they are argued to have on the lives and livelihoods of poor households, women, and children.

The widening income inequalities and heightened levels of poverty that accompanied early neoliberal reforms have forced many proponents to reconsider the benefits of approaches that emphasize market fundamentals with minimal state intervention. In the global South, this recognition led to the replacement in 1999 of SAPs with poverty reduction approaches that rely on governance structures that encourage greater consultative partnerships between international lenders, borrowing governments, and civil society groups. Critics, however, remain skeptical of the extent to which the philosophies that guide the new Poverty Reduction Strategy Papers differ from those that shaped SAPs. As a number of

A worker in Panama City marches and holds a sign that reads, “Down with neoliberal politics,” May 30, 2002. Thousands of workers, teachers, and students marched to the presidency building to protest against a project to privatize the Social Security Service.

scholars state, these programs still rely on the approval of the World Bank and the IMF before they can be instituted, and approval has remained tied to a vision of development that privileges free market economic growth over poverty reduction. Similar observations have been made by the geographers Adam Tickell and Jamie Peck, who argue that while neoliberalism is no longer crudely focused on rolling back the state, it is increasingly evolving into a set of technocratic policies aimed at rolling out and consolidating the logic of the market in a wide variety of social and economic institutions through state intervention and regulation. In keeping with this observation, geographers also argue that contemporary neoliberalism is evolving into a type of governmentality that naturalizes and embeds market mechanisms into every aspect of everyday life and simultaneously

produces individuals who regulate themselves to conform to this logic.

From the ongoing debates, it is clear that rather than monolithic and static, the neoliberal discourses and practices have been dynamic, adapting to shifting economic conditions, as well as the critiques of civil society groups. Yet to argue that neoliberalism has lost its relevance as a meaningful term would be to ignore the priority that these policies continued to give to free markets and to those best able to compete in them.

NEO-MALTHUSIANISM

Thomas Malthus was an English clergyman who popularized a set of ideas on population and agricultural growth in the early 19th century. *Neo-Malthusianism* refers to the variant forms of these ideas that have appeared in scholarly and scientific publications, shaped various kinds of policy making, and often exerted considerable influence on popular discourse over the years.

Malthus's *An Essay on the Principle of Population* was published anonymously in London in 1798. It challenged the optimistic writing of Enlightenment giants Godwin and Condorcet, who believed that scientific progress and refinement of social institutions would ensure enough food for all. Malthus instead pointed to “fixed laws of our nature,” specifically that “population, when unchecked, increases in a geometrical ratio . . . subsistence increases only in an arithmetical ratio.” Since this imbalance was intrinsic to human ecology, food shortage would be a permanent force shaping society and limiting population. Therefore,

he argued, aid to the poor and hungry would only succeed in forestalling the population-limiting effects of food shortage, ultimately making for more people who would inevitably suffer from conflict, sickness, and potential starvation.

Developments since Malthus's time have not fit Malthus's postulates well. Various social institutions, government policies, education, and economic development are now known to effectively curb population growth, and total fertility rates have plummeted worldwide (including throughout most of the developing world since the 1960s). Agricultural output has outpaced human food needs, due largely to the use of external inputs that were largely unknown in Malthus's day: nitrogen fertilizer, mechanization, breeding, pesticides, and information technology. The Food and Agriculture Organization predicts agriculture to continue to outpace food needs for decades; yet hunger continues to stalk areas of the developing world, and food insecurity affects significant numbers in industrialized countries. In 1996, the economist Amartya Sen was awarded the Nobel Peace Prize for showing how little overall food supply had to do with famine. Malthus—as Cohen (1995) bluntly put it in *How Many People Can the Earth Support?*—“has been wrong for nearly two centuries” (p. 429).

Yet Malthus's basic view of population growth as a persistent driver of food shortage has continued to exert widespread and persistent influence on a long and varied history of theories, schools of thought, movements, and policies. Much of this persistent power is due to its malleability and the fact that its basic tenets and implications can be adjusted to changing agendas.

For instance, in the early 20th century, neo-Malthusians took Malthus's stress on the overabundance of poor people to support anti-immigrant organizations and policies in the United States. Academic books stressed the dangers posed by the reproductive urges of “inferior races,” including Jews and the Irish. In the 1960s, neo-Malthusians, such as the Club of Rome, sounded the alarm over the world's high population growth rate and its impacts on resources and the earth's capacity to sustain rising numbers of people. Neo-Malthusianism shaped Cold War thinking in the United States, attributing the spread of communism to high population densities in Asia. These fears were particularly focused on India, where

post–World War II peasant movements were taken as warnings that India might go the way of China. Through the PL-480 program, large amounts of American grain were exported to India well into the 1960s to check the spread of communism while absorbing U.S. grain surpluses.

Beginning in the mid 1990s, neo-Malthusianism helped fill the void in post–Cold War thinking, with academic writers and journalists stressing environmental security as the new driver of Third World conflict. This surge of neo-Malthusianism went beyond food and depicted local shortages of various resources as the principal driver in local conflicts. Robert Kaplan’s lurid essay “The Coming Anarchy” popularized this perspective in public and policy circles, although detailed case studies by geographers and anthropologists showed that such conflicts tended to be driven by other, non-demographic and nonlocal factors.

Most recently, neo-Malthusianism has played a key role in debates over genetically modified crops. In the late 1990s, following Europeans’ rejection of genetically modified foods, writing by both corporate and academic biotechnologists began to raise alarms about population growth and impending food shortages in developing countries, FAO (Food and Agriculture Organization) projections notwithstanding, touting genetic modification as a solution. As with other phases of neo-Malthusianism, this invokes the alarm of population outstripping food supply but adds new elements suited to the times.

NETWORK ANALYSIS

Network analysis refers to the spatial analysis of transport (roads, railroads, airlines) or utility (pipeline, Internet) networks, and it has also been used for examining and optimizing hierarchical relationships within a set of places linked by flows. Network analysis abstracts the fundamental components of a network to depict the connections between places. A network is made up of nodes (locations, or origins and destinations of flows) and links (physical connections or flows between nodes). Loops may be present and allow multiple paths between a pair of nodes. A network may be planar, with nodes at the junctions of all links, or nonplanar, in which links may cross one another without an intersection. Depicting a network at the interurban level is generally straightforward, using cities, ports, or airports as nodes, while representations at the intraurban scale require more care. Street intersections may be used as nodes, though some uses may be more abstract, with nodes representing zones and links approximating flows between them. The link-node structure of a network can be shown as a matrix, and it is common for networks to be specified as a connectivity, impedance, or origin-destination (flow) matrix. These matrices in turn allow for the calculation of shortest-path algorithms and related methodologies, such as aggregate or topological accessibility.

Early Applications in Geography

Network analysis is derived from the mathematical field of graph theory, a branch of topology. Graph theory focuses on the connectivity of a network, not on its visual appearance. Both were introduced

into geography in 1960 by William Garrison, who examined the structure of the Interstate Highway System in the southeastern United States. Analysis of transport networks became common in the 1960s. The centrality of cities was evaluated using a connectivity matrix, and several network measures, such as alpha (the ratio of the number of loops to the maximum possible), beta (the ratio of links to nodes), and gamma (the ratio of actual links to the maximum possible in a planar network), were also developed. They measure the connectivity of the network in different ways, though their usefulness and uniqueness has been debated.

The arrival of network analysis in geography was closely related to the quantitative revolution and its search for regularities that would allow for spatial laws. Studies using network analysis attempted to relate socioeconomic indicators of various countries to their road or rail network structure in the search for universal regularities about development. Other studies attempted to create predictive models of network growth based on observed patterns in their structural change over time. While many early studies were rigorously mathematical and theoretical, later network analyses rarely used the terminology or notation of graph theory.

Network analysis became essential to the new field of transport geography and was compatible with other new quantitative methods in the field, such as spatial interaction modeling. Peter Haggett and Richard Chorley's (1969) book *Network Analysis in Geography* marks the high point of the early network analysis approach in geography. It examined topics such as topological structures, network shape, location, flows, and growth and transformation of networks. These were applied to a wide variety of human and physical geography topics, such as rivers, roads, airlines, and economic linkages between cities or regions. All were treated as instances of network development and amenable to similar kinds of theories and methodologies. Network analysis declined in importance during the 1970s, though it has remained in transport geography textbooks.

Later Developments

In the 1980s, network analysis reemerged as a significant topic due to recognition of the importance

of hierarchy in networks. This trend was stimulated by the phenomenon of airline deregulation and the rise of hub-and-spoke networks with many indirect connections between nodes. The location of a node within these networks and the design of optimal network structures to maximize flows or minimize the costs of flows have become an important part of network analysis and have been extended to many transport modes and types of spatial interactions. Recent work often includes a focus on the vulnerability of a network to disruption, such as the loss of a critical node or link following a disaster.

In the 1990s, small-region (also called *small-world*) networks have continued to be explored in modeling hierarchies and in optimization. In these types of networks, a few nodes have a far greater level of connectivity than would be expected and so allow for shorter routes between average nodes within a network. Transportation networks are only a small part of these studies, as a wide range of biological, engineering, and social phenomena have been investigated for small-world network traits. The mathematical properties of such networks are generally considered to be universal for all such instances, much as in the early network analysis work.

Network Analysis in GIS

While theoretically simple, calculating network measures and shortest routes for all but small networks is extremely labor intensive. These applications were reliant on computers from the very beginning, and the widespread use of GIS has led to an enormous increase in the ease of use of these methodologies. Digital data for street and other networks are readily available, and the network or arc-node data model for GIS allows network analysis. Shortest-path algorithms are easily calculated, and new features such as multimodal and multiscale networks have been developed. Network versions of market area models, spatial interaction, location-allocation, aggregate accessibility, space-time accessibility, and other standard geographic applications have been created. These procedures use road distance or driving time to represent distance instead of Euclidean or straight-line distance. Due to GIS, network analysis has moved away from its original mathematical and

theoretical basis toward a geocomputational perspective using non-Euclidean space.

NETWORK DATA MODEL

Route planning is a common task. A route plan used to be marked on a paper map, but now it can be easily done on a digital road network using an automotive navigation system or a geographic information system (GIS). A network is a system of linear features that has the appropriate attributes for the flow of objects. A road system is a familiar network; other networks include railways, public transit lines, bicycle paths, utility lines, and streams.

A network data model consists of geometries and attributes. The basic geometric features are edges (links) and junctions (nodes). An edge refers to a line segment defined by two end points. A junction refers to a point, where lines meet or intersect. To be used for route planning, a network must be topology based. Network topology is explicitly expressed through graph theory (a branch of mathematics): edges are directional; edges meet or intersect perfectly at junctions; and if an edge joins two junctions, the junctions are said to be adjacent and incident with the edge. Moreover, the adjacency and incidence relationships are built into matrices. Stored as tables in a GIS, these matrices form the core of a logical

network, which works along with the network geometries for applications such as route planning.

Network attributes include cost impedances, turns, one-way or vehicular restrictions, hierarchy, and elevation fields. Cost impedances relate to edges and turns. Link impedance is the cost of traversing an edge. A simple measure of the cost is the edge's physical length. But the length may not be a reliable measure of cost, especially in cities where speed limits and traffic conditions vary significantly along different streets. A better measure of link impedance is the travel time estimated from the length and speed limit of an edge. For example, it takes 20 minutes to travel 10 mi. (miles) on a road with a speed limit of 30 mi. per hour. A turn is a transition from one edge to another at a junction. Turn impedance is the time it takes to complete a turn. Turn impedance is directional. For example, it may take 5 s (seconds) to go straight or make a right turn and 30 s to make a left turn at a stoplight. A negative turn impedance value usually means a prohibited turn, such as turning the wrong way onto a one-way street. Cost impedances are entered in designated fields. For example, a field called *Minutes* can assign link impedance in travel time.

One-way streets or vehicular restrictions (e.g., “no left turn”) can also be denoted in special fields. For example, “T” in a field called *one-way* means that a street segment is one-way, and “F” means that it is not. The direction of a one-way street is determined by the beginning point and the end point of the edge. Hierarchy refers to a classification of roads, such as interstate, state, and county highways. Given a multiple-level hierarchy, the logical network can use it to optimize route solving on large transportation networks. Overpasses, underpasses, bridges, and tunnels are typically represented as planar features with elevations. Elevations, in this case, are not altitudes but the logical levels of roadways. For example, to show First Avenue crossing Oak Street with an overpass, the elevation value of 1 can be assigned to First Avenue at the crossing, indicating that the overpass is on First Avenue.

Both edges and junctions are vector data represented by points and their *x*-, *y*-coordinates. Vector data in a GIS can be either georelational or object oriented. As examples, shapefile is georelational, and geodatabase is object oriented.

Compared with a shapefile-based network, a geodatabase network has a more flexible data structure, which allows network topology to be embedded in object-oriented representations. Unlike a shapefile-based network, which can only have one edge source, a geodatabase network can have multiple edge sources (e.g., roads, rails, bus routes, and subways) and can connect different groups of edges at specified junctions (e.g., a subway station junction connects a subway route and a bus route).

Networks with topology are useful for a number of applications of which the best known is shortest-path analysis. Shortest-path analysis finds the path with the minimum cumulative impedance between junctions on a network. The path may connect just two junctions—an origin and a destination—or have specific stops between the junctions. Shortest-path analysis can help a driver plan routine trips between home and workplace, a van driver set up a schedule for dozens of deliveries, and an emergency service connect a dispatch station, accident location, and hospital.

Closest facility and allocation are extensions of shortest-path analysis. To find the closest hospital, fire station, or ATM, an algorithm first computes the shortest paths from the select location to all candidate facilities and then chooses the closest facility among the candidates. Allocation is a study of the spatial distribution of public facilities such as fire stations, schools, or even open spaces (in case of an earthquake) on a network. Because the distribution of public facilities defines the extent of their service area, spatial allocation analysis can measure the efficiency of these facilities.

Address matching, also known as geocoding, requires the use of a street network and attributes such as the street name, address range, and ZIP code for each street segment. It compares a street address with the network data, interpolates the address location on the network, and plots the address as a point feature. Address matching is a service offered by Web browsers as well as many public and commercial Web sites.

Shortest path, closest facility, spatial allocation, and address matching are some of the applications using a network. With GIS being increasingly integrated with the Internet, GPS (global positioning system), wireless technology, and Web service, we

can expect to see more interesting and dynamic network applications in the future.

NEW INTERNATIONAL DIVISION OF LABOR

Capitalist development has always occurred unevenly—spatially, sectorally, and temporally—producing differential degrees of industrialization and varying modes and levels of integration into the world economy. Since the 1970s, however, there has been a widespread recognition that a fundamental transformation (now commonly understood as globalization) is taking place in the conditions of capitalist accumulation and expansion of capital on a world-historical scale. The term *new international division of labor* (NIDL) was coined by theorists seeking to explain the spatial shift of manufacturing industries from advanced capitalist countries to developing countries—an ongoing geographic reorganization of production, which finds its origins in the formation of the “world market for labor” and “world market for industrial sites” famously analyzed by the German political economists Folker Fröbel, Jürgen Heinrichs, and Otto Kreye. Under the “old” international division of labor, underdeveloped areas were incorporated into the world economy principally as suppliers of minerals and agricultural commodities. A growing emphasis on factors such as the internationalization of production, the greater

sway of transnational corporations (TNCs), and the enhanced mobility of capital facilitated by modern communications technology and liberalization has generated a transition toward an NIDL in which low-wage developing countries increasingly provide sites for labor-intensive industries that manufacture goods for sale in the world economy.

Theories of the NIDL assign a major role to TNCs as the orchestrator of a global reallocation of manufacturing away from advanced countries toward the developing countries. Varying in emphasis from a “neo-Smithian” focus on changes in the world market to a “neo-Ricardian” one on capital exports, theories of the NIDL have sought to explain a dual pattern of “industrialization” in the developing countries and “deindustrialization” in the advanced countries. In seeking to explain this pattern, the concept of an NIDL focuses on the determining roles played by (a) the development of a worldwide reservoir of potential labor power; (b) the development of the labor process in manufacturing, which has led to the decomposition of production processes into elementary units and the deskilling of the labor force; and (c) the development of the forces of production in the fields of transport and communication, which has made industry less tied to specific locations. These preconditions, together with the desire of TNCs to maximize profits, result in industrial relocation to employ what Fröbel, Heinrichs, and Kreye described as readily available, inexpensive, and “well-disciplined” labor. One key argument of NIDL theorists is that with new technologies, especially space-shrinking systems of transport and communications, sites for manufacturing are increasingly independent of geographical distance. Capital now not only searches for fresh markets but also seeks to incorporate new groups into the labor force.

Thus, it was initially through the export processing zones of the globalizing electronics and textile industries that many women from the developing world have become part of the international working class. Through the exploitation of their labor power within world market factories situated in developing, low-wage countries, specific regions within what was formerly known as the *Third World* became manufacturing sites for consumer markets in the advanced countries

through transnational production arrangements involving foreign direct investment or international subcontracting. In that the term *global factory* refers specifically to the sites of production in transnational production arrangements, it is not limited to “factories” per se but also includes petty commodity producers, often toiling in “informal” establishment such as sweatshops and home industry. Despite this diversity in possible employment forms, the key argument of NIDL theorists is that working conditions in the global factories situated in developing countries tend to be poor on account of their *raison d’être*—to enable TNCs from the core advanced countries to redeploy their capital for goods production to low-cost labor sites in the periphery, where TNCs and their subcontractors extract surplus value from Third World workers.

The signal contributions of theories of the NIDL have been to highlight the growing power of TNCs (in particular, their capacity to optimize differing opportunities for profit by decentralizing production across the globe) and to demonstrate that industrialization and deindustrialization are in fact related phenomena. Indeed, the concern over deindustrialization, unemployment, and the proliferation of low-wage service sector jobs in the advanced countries partly reflects the success of newly industrializing countries in relatively labor-intensive manufacturing markets and the export of semiskilled industries jobs to lower-wage countries under the aegis of TNCs. Critics of the NIDL thesis, however, argue that it overstates the significance of “cheap labor” as the propellant for capital movements across the globe, particularly geographical shifts of manufacturing production. There is no gainsaying the spurt of industrialization that has taken place over the past half-century in the developing (Third World) countries, and in particular in the four “Asian dragons” (Hong Kong, Singapore, Taiwan, and the Republic of Korea), the three “Asian tigers” (Malaysia, Thailand, and China), and what has come to be known as the BRIC (Brazil, Russia, India, and China). Still, the point is that although the contribution of such countries to global manufacturing output has increased, focus on an NIDL may exaggerate the extent of change that has taken place in the world economy, in which the large majority of developing-country workers are still overwhelmingly producers of raw

materials whose relationship to the world economy continues to be defined by the old rather than the new international division of labor.

NEWLY INDUSTRIALIZING COUNTRIES

Newly industrializing countries (NICs), sometimes also called *newly industrializing economies*, are a group of states in the developing world that developed substantial manufacturing bases in the late 20th century. Definitions of this group vary, but they are generally taken to be states that exhibited rapid and sustained increases in GDP, incomes, and industrial employment. Most are located in Asia, although several are found in Latin America as well (Figure 1). Other definitions of NICs include South Africa and Turkey.

The emergence of the NICs has significant implications for development theory as well as the lives of billions of people in the world.

Modernization theorists trumpet their success as proof of the wonders of the market. Whereas dependency theorists maintained that the diffusion of manufacturing from the First World to the Third was unlikely or impossible, the rise of the NICs in the 1970s indicated that the status of the developing world was hardly fixed or static. In terms of world-systems theory, the NICs pointed to states that moved from the global periphery to its semiperiphery.

Common to many NICs was a shift from import substitution to export-led industrialization, in which tariffs and quotas on imports were reduced, foreign direct investment (FDI) was encouraged, and exports aggressively promoted, including through the use of export processing zones. Such moves were often justified by an appeal to neoclassical economic notions, such as comparative advantage. Many states such as South Korea and Taiwan began to develop a capacity in footwear and textiles by the 1960s, moving into more capital-intensive, higher-value-added sectors, such as automobiles, ships, steel, precision machinery, and electronics over the next several decades.

The East Asian NICs are perhaps the most representative members of this group. Following the example set by Japan, which industrialized early, several generations of Asian NICs began to imitate the Japanese model in the famous “flying geese” formation of development. The original “Four Tigers” or “Minidragons” included South Korea, Taiwan, Hong Kong, and Singapore (the latter two former British city-state colonies), all of which developed high-quality educational systems, infrastructures, and government policies conducive to capital accumulation. Some observers point to the legacy of Japanese occupation in this regard, while others note the importance of Confucianism in producing a compliant labor force, as well as a high domestic savings rate. Yet others argue that the NICs’ growth had little to do with a “free market” and much to do with oppressive and authoritarian government strategies that repressed labor. South Korea and Taiwan, for example, were run by military dictatorships for much of the early period of their growth. Yet another factor was the active intervention of the United States in the region during the Cold War (including defense subsidies and

Figure 1 Newly industrializing countries in 2008. Definitions of the NICs vary, but all exhibit rapidly growing economies and exports.

preferential trade agreements), an advantage not afforded to other regions, such as Latin America. Singapore, in particular, developed not only as a center of light manufacturing but also thrived with a very large port and a growing capacity in financial services and telecommunications to become the second wealthiest country in Asia.

The second generation of East Asian “dragons” included Thailand, Malaysia, and Indonesia, all of which pursued the model set by the first generation. To varying degrees, with considerable inequalities within them, these countries developed manufacturing capacities in textiles, automobiles, electronics, and other sectors, often using docile young female workers in foreign-owned assembly plants that resembled Mexico’s *maquiladoras*. Malaysia’s Vision 2020, in which it sought to become a fully industrialized state by that year, included making it the world’s leading producer of semiconductors and small motors for appliances. In all, tens of millions of people were pulled out of poverty to create a growing middle class with higher incomes and purchasing power, although the Asian financial crisis of 1997–1998 revealed that such growth was not inevitable. In all, rising automobile ownership led to increasingly congested cities. All three of these states, to different degrees, have also had autocratic

governments that often take a dim view of civil liberties and dissent.

Of course, looming over all the NICs is China, whose rapid growth since the mid 1970s has transformed the world’s most populous country and made it an enormous economic power. The economic reforms initiated by Deng Xiaoping proved to be quite successful at reintegrating the country back into the world economy, and China has enjoyed growth rates often exceeding 10% annually to become the world’s second largest economy today. Most of China’s growth has been concentrated along its eastern seaboard, where Deng established the famous Special Economic Zones. The most rapidly growing part of China has been the southern province of Guangdong, which has benefited from close ties to Hong Kong entrepreneurs and financiers. China also attracted enormous quantities of foreign direct investment and as the world’s largest exporter, enjoyed sizable trade surpluses, particularly with the United States. Today, China is the world’s leading producer of electronics, apparel, toys, steel, cement, and cotton. As in Taiwan, Korea, and Singapore, the Chinese economy has also steadily moved into higher-value sectors, such as finance. At current rates of economic growth, China may surpass the GDP of the United States by 2050. However, such

growth has simultaneously created huge disparities between the rich and the poor, tens of millions of desperate migrants who have evacuated the interior for the opportunities along the coasts, and an oppressive government much given to censorship, suppression of dissidents, and violations of human rights.

India, too, shows signs of becoming an NIC. The world's second most populous country, with huge reservoirs of poverty, nonetheless exhibited consistent economic growth rates when it abandoned its earlier isolationism and welcomed foreign investment. The prominence of Bengaluru, the heart of the Indian electronics and software industry; the growth of call centers; the financial and cinema complex in Mumbai; and India's growing middle class all point to what will be an increasingly formidable economic power in the future.

Latin American NICs include Brazil, Mexico, and Chile. Brazil's growth, centered on heavy manufacturing such as aerospace in the 1970s, was crippled by the oil shocks and resulting explosion of foreign debt. Likewise, Mexico, which staked its fortunes on petroleum, suffered with the price declines in the late 20th century. The rise of the maquiladoras, now Mexico's largest source of foreign revenues, led to growing capacity in the assembly of textiles, electronics, and automobiles, primarily in the north of the country and often at the cost of great human suffering. The impacts of the North American Free Trade Agreement in this context are complex and contradictory. Chile, since the vicious coup d'état that ousted Allende in 1973, became something of a model of neoliberal experimentation under the brutal reign of Pinochet; nonetheless, Chile has enjoyed the most rapid economic growth in Latin America for several decades, and it exports textiles and wine, among other goods.

The growth of the NICs has not been unproblematic. In all of them, rapid growth has been accompanied by mounting social and spatial inequality, sometimes severe, as well as social and cultural problems associated with rapid transformation. As some states adopted neoliberal policies, safety nets for the poor were often left in disarray.

In addition to trade policy (i.e., export-led industrialization), the growth of the NICs reflects several other factors. Most enjoyed land reform to

one extent or another (e.g., via the Japanese occupation or the Korean war), which broke up feudal rural elites, improved agrarian opportunities, and helped minimize rural-to-urban migration. All had governments that encouraged development, not regulation, with clear long-term priorities and consistent, centralized, growth-oriented policies. All minimized their reliance on foreign funding and encouraged domestic savings, although all NICs encouraged FDI. All sought to move as quickly as possible from low-wage, low-skilled, low-value-added exports to progressively higher wage, higher-value-added ones.

To what degree is the success of the NICs replicable elsewhere? The answer to such a question, which has enormous implications for Third World development possibilities, in no small part depends on the theoretical perspective one adopts to explain the NICs' successes. For advocates of modernization theory, and its neoliberal reincarnation, the NICs represent the success of unfettered capitalism, which, with proper attention to trade policy and finance structures, can be ultimately reproduced virtually anywhere. To advocates of dependency theory, the NICs represent a unique, historically specific set of conditions that cannot be replicated easily. In this reading, the NICs' growth was led by the state, not the market, and such growth did not materialize in many other countries (e.g., the Philippines). And finally, to world-systems theorists, the NICs represent but one moment in the long historical process by which various states slide up and down the hierarchy of countries that defines the global division of labor at different moments in times; that is, their success is possible elsewhere, but not likely. Such concerns notwithstanding, many other countries have attempted to imitate the NICs, with varying degrees of success.

NEW URBANISM

New urbanism is a postmodern American urban design and planning movement that began in the 1980s as a challenge to modern urban form and automobile-centered suburban development. The new urbanism movement seeks to redefine the American dream through the creation of walkable neighborhoods modeled after traditional American small towns. Placing the pedestrian at the core of neighborhood design, the movement proclaims a rebirth of sociability, civility, and improvement in public health through walkability and physical activity long thwarted by the design of conventional suburbia.

The roots of new urbanism converged in 1993 in the Congress for the New Urbanism and can be traced to two distinct urban design perspectives: traditional-neighborhood development (TND)

and transit-oriented development (TOD). Both perspectives criticize conventional land use zoning for segregating urban activities and making car travel indispensable resulting in high-energy consumptive lifestyles. In opposition to the proliferation of single-family-home subdivisions devoid of a public realm, sidewalks, and civic amenities, both TOD and TND prescribe the creation of small, walkable neighborhoods with a diverse mix of residences, shops, workplaces, and public facilities reachable within a 5- to 10-minute walk. The two design approaches differ in the way they internally organize development and in the way they articulate the neighborhood with the rest of the urban fabric. TND, which originated on the east coast, is focused on an identifiable town center and laid out on a dense grid of boulevards, narrow streets, alleyways, and plazas. In contrast, TOD, which originated on the west coast, is focused on a transit station to which all major streets converge. In its prototypical formulation, TND commercial and residential blocks are small with small building footprints, where houses with front porches face the street while garages are tucked on alleyways behind houses. TOD is similarly compact in design; however, while TND relies on existing freeways and arterials for metropolitan travel, TOD, organized around transit stations, depends on high-quality transit service for effective substitution of car trips for transit trips—a hallmark of the sustainability claims of the movement.

Roots of the Movement

TND is associated with the 1980s European critique of modern urbanism and functionalist urban planning (e.g., segregation of land uses). This critique was spearheaded by Léon Krier and subsequently endorsed by Prince Charles's urban village movement in the United Kingdom. Krier denounced metropolitan growth and the automobile as destroyers of city life, a sense of community, and the civic realm and advocated the reconstruction of cities into a federation of semi-autonomous pedestrian-scaled urban quarters, where foot travel would substitute for motorized travel, residents would be integrated by occupation, age, and socioeconomic class, a rebirth of

cottage industries would supersede commercial strips, and true civic culture would replace the boredom and alienation of the suburb. Krier's indictments were preceded in the United States by Jane Jacobs's 1960s manifestos against suburbia, urban renewal, and zoning, and by Allan Jacobs and Donald Appleyard's livable-places manifesto in the 1970s. However, Miami architects Andrés Duany and Elizabeth Plater-Zyberk were the first to heed Krier's call for traditional urbanism in the design of Seaside, in Florida's Panhandle. Duany and Plater-Zyberk's efforts to architecturally and urbanistically code in Seaside the character of traditional small towns paid handsomely. This iconic 80-acre resort town became the prototypical TND, widely showcased in architecture, real estate, and news media, including the Hollywood movie *The Truman Show*. The town's incredible real estate success—in 20 years property appreciated more than a hundredfold its original value—rather than its designers' loftier objectives of socioeconomic integration and reduced car use, propelled TND into a new paradigm of planning and community building primarily on greenfields. The Kentlands, a 352-acre community in Maryland designed by Andres Duany and Elizabeth Plater-Zyberk in 1988, and later in 1994, Disney's 5,000-acre town of Celebration, Florida, designed by Robert A. M. Stern and Jaquelin Robertson, became exemplars of traditional neighborhood development on a grand scale.

The west coast approach emerged in the 1970s from

among several strands of the ecological critique of the modern metropolis, conventional suburban development, and postindustrial society. One

form of freestanding TOD satellite towns. Laguna West, an 800-acre pedestrian-friendly community built around a lake, town center, and future

strand was the sustainable-communities design movement pioneered in the 1970s by Michael and Judy Corbett with the building of Village Homes in Davis, California—one of the first communities to feature edible gardens, affordable housing, and solar energy and natural drainage design. In the 1980s, the movement's regional scope and design synthesis took shape in San Francisco with Sym Van der Ryn and Peter Calthorpe's work on ecologically minded urban design. However, mass transit, rather than green design, inspired Peter Calthorpe and Douglas Kelbaugh to formulate the "pedestrian pocket," a residential neighborhood placed within walking distance of transit, jobs, schools, shops, parks, and civic amenities. Pedestrian pockets, the forerunners of TOD, were conceived as a regional design strategy for reducing driving, preserving open space, increasing the supply of affordable housing, and reining in urban sprawl. By the 1990s, Peter Calthorpe expanded the pedestrian pocket into TOD, which like earlier streetcar suburbs would be located on a trunk line or on a feeder bus line. As nodes of a transit network and components of a regional planning strategy, TODs can be designed for urban infill or redevelopment, new greenfield in suburban areas, or beyond the city's edge in the

Orenco Station, Portland, Oregon

transit station in Sacramento, California, was the first “on-ground” test of the TOD idea. However, Laguna West’s still infrequent bus service makes it incomplete as a TOD and still highly dependent on the automobile. Orenco Station, a 190-acre greenfield community built on Portland’s Westside light-rail line, features a retail-and-office town center and a variety of housing types and is considered one of several successful TODs built to date.

As evidence of the movement’s widespread influence, the 2008 *Directory of New Urbanism* boasts 520 places, 3,000 firms, and 4,450 contacts—a burgeoning national-community-building industry, which in 2003 already counted 230 places built or under construction and 309 in some planning stage. However, despite its rapid growth and acceptance, less than 12% of these places were TOD or Hope IV public housing projects, lending support to the view that new urbanism’s larger transportation sustainability and social justice goals have remained somewhat limited. TND communities are typically affordable to the high-end consumer; although walkable, they are still highly automobile dependent, and the majority are located in greenfield sites. Consequently, some critics charge the new urbanist industry with promoting a new type of sprawl, quaint, walkable, and

more compact but expensive, still car dependent, and predominantly located at the urban edge. Despite these criticisms, new urbanism offers a welcome alternative to the ubiquitous commercial strip and generic residential subdivision.

NITROGEN CYCLE

The nitrogen cycle refers to the geophysical, chemical, and biological processes involved in converting atmospheric nitrogen into a form that plants can use, recycling those nitrogen compounds within ecosystems, and returning them to the atmosphere. Of all the fundamental biogeochemical cycles, the nitrogen cycle is the most complex as it depends on the balanced activity of several different kinds of organisms, ecosystems, and atmospheric processes. It is also the cycle most affected by human activity. Indeed, the manipulation and transportation of nitrogen compounds by humans is now a major component of this fundamental Earth system, transforming what was once a predominantly local cycle into more of a regional and even global flow of material.

Flows of nitrogen through the biosphere are important because the availability of nitrogen plays a regulatory role in the production of biomass. In regions with sufficient water and sunlight, the production of biomass is generally limited by the quantity of chemically active nitrogen available. Although Earth is encapsulated by a nitrogen-rich atmosphere, that nitrogen is locked away in strongly bonded molecules of N_2 . For atmospheric nitrogen to be made available to plants, those bonds must first be broken so that the nitrogen can become part of another chemical compound. In nature, nitrogen-fixing bacteria—and to a much lesser extent, lightning—perform that role. (The word *fixing* can be traced back to the alchemists, who used the word *fixed* to describe what happened when a gas was converted into a liquid or solid.)

In a mature ecological system free of agriculture, the activity of nitrogen-fixing bacteria is more than sufficient. Existing nitrogenous compounds continually get recycled as leaves, grasses, fruits, and seeds fall to the ground and decompose into ammonia (NH_3) and other compounds. Then, in the soil, nitrifying bacteria (as opposed to nitrogen-fixing bacteria) convert the ammonia into nitrite (NO_2^-) and nitrate (NO_3^-), the latter being a highly soluble form of nitrogen that plants can take in through their roots. Nitrogen-fixing bacteria are only needed to make up for the small

losses that occur when nitrogen-containing compounds vaporize, leach away, or get carried away by streams to wetlands, floodplains, and the sea. In soils saturated with water, other types of bacteria, known as denitrifiers, convert nitrogenous compounds back to gases, balancing the activity of nitrogen-fixers.

The emergence of stationary agriculture altered local flows of nitrogen. Transporting nitrogen-rich protein away from the same agricultural fields year after year meant that large quantities of scarce nitrogenous compounds were also being carried away. This nitrogen had to be replenished if stationary farming were to be a long-term endeavor, and much of agricultural history revolves around societies learning, by trial and error, how to accomplish this feat. In many agricultural societies, the cultivation of legumes—which work symbiotically with nitrogen-fixing bacteria—emerged as an important way to replace that nitrogen. Even then, however, the availability of nitrogen remained a limiting factor. Nitrogen-fixing bacteria could replace losses of nitrogen only so quickly, and in the long term, farmers could not produce more crops than bacterial activity allowed. Until the 19th century, societies had no choice but to live within that limit.

Starting in the 19th century, agricultural chemists in Europe became aware of the role that soil nutrients played in plant growth, and farmers began experimenting with a variety of manures and soil additives. By mid century, merchants in Europe and the United States were importing large amounts of nitrogen-rich guano from South America and securing significant quantities of ammonium sulfate, a by-product of coal, from industrial firms. Farmers applied both as a fertilizer. This movement of material represented new pathways for flows of nitrogen. In the case of guano, nitrogen fixed by bacteria in a distant continent began flowing into the soils of Europe and North America. And when farmers applied coal-based ammonium sulfate to their land, their soils began to receive nitrogen fixed by bacteria millions of years ago.

Eventually, in the early 20th century, European engineers and scientists figured out how to bypass nitrogen-fixing bacteria altogether, eliminating previous limits on the production of protein. In particular, the German Haber-Bosch process for

fixing nitrogen industrially—accomplished by converting N_2 and H_2 into ammonia at high temperatures and pressures in the presence of a catalyst—is credited with making inexpensive sources of fixed nitrogen widely available. Today, the world could not produce the quantities of grain and beef that people now consume without industrially manufactured nitrogenous fertilizers, at least not without a radical restructuring of how societies are organized. In addition, when that protein is consumed, nitrogenous compounds are discharged in urine and feces. After passing through feedlot drains, sewage treatment plants, and septic systems, much of this nitrogen is released into waterways. Complicating matters further are additional flows of nitrogenous material from heavily fertilized agricultural soils, flows of nitrogen oxides out of power plants and tailpipes, and the loss of wetlands that host denitrifying bacteria.

For all these reasons, the nitrogen cycle that exists today is quite different from that which existed before stationary agriculture, both in magnitude and spatial complexity. In addition, in the nitrogen cycle of the 21st century, denitrification does not appear to be keeping up with the amount of nitrogen being placed into circulation by industrial processes. As a result, more nitrogenous compounds are reaching the ocean and seeping into groundwater than a century ago. One outcome is the creation of hypoxic dead zones near the mouths of major rivers, which occurs due to excessive quantities of nutrients giving rise to blooms of algae. The eventual decomposition of this organic material consumes the dissolved oxygen that fish need to live. Nitrates carried by water into the ground can also be a problem: High nitrate levels often prevent aquifers from being used as safe sources of water. Increased denitrification is not necessarily desirable either, as the gases emitted include a greenhouse gas (nitrous oxide, N_2O) and a gas (nitric oxide, NO) that reacts with ozone in complex ways.

Today, therefore, we interact with the nitrogen cycle every time we eat protein, flush a toilet, turn on a light, drive a car, apply fertilizer, and, in general, participate in the basic activity of an industrial society. Our activities have resulted not only in larger quantities of chemically active

nitrogen being placed into circulation but also in nitrogenous compounds following new pathways and accumulating in a variety of biogeochemical reservoirs. Many flows of nitrogen are now influenced by policy tools, such as discharge permits, emissions trading programs, watershed management plans, best-management practices for farms, wetland restoration efforts, rules governing the reuse of biosolids, and the creation of wellhead management zones. This management of human-created flows of nitrogen is another way in which human activity has become an important component of the nitrogen cycle.

NOMADIC HERDING

Derived from the Latin word for shepherd (*pastor*) and the Greek word for a wanderer seeking pasture (*nomas*), pastoral nomadism describes a specialized form of mobile animal husbandry. This production system is extensive, and animals are often moved over a large area in an annual cycle. These nomadic herders exploit areas that are too extreme (too dry, steep, cold) to sustain settled agriculture. Since the middle of the 20th century, changes in pastoral zones have discouraged nomadic herding and resulted in degradation of those areas where significant nomadic pastoral communities continue to exist. This entry

first describes the nature of nomadic herding, the structure of herding groups, and the nature of their use of resources. It then describes the impact of modernization on nomadic herding.

Nomadic herding uses animals as intermediate converters of vegetation to produce meat, dairy products, fiber, hides, and other commodities. Modern intensive grazing systems bring food to the animals, limit animal movement, and promote quick growth to slaughter weight. In contrast, traditional pastoral nomads move their animals to food and water. Animals herded nomadically expend large amounts of energy reaching distant fodder. This produces a tougher, leaner, healthier, and tastier meat but lengthens the time required to achieve market weight and requires the herding family to accompany the animals to distant pastures. Nomadic herders achieve mobility by reducing material possessions to essential equipment, living in tents, engaging in annual migrations, and moving base location many times during the year.

Vertical and Horizontal Movements

Movement takes place within a regional spatial framework rooted in local ecology. To support their flocks, all pastoral nomads must control access to seasonally available resources, which are seldom available in one small area for an entire year. Herders must migrate to find necessary resources in different places at various times of the year. The location of water and forage is well-known to pastoralists, and movement to use these resources is regular, not random. Pastoral nomads do not wander aimlessly seeking sustenance, a classic “outside” perception of their movements, but rather regularly revisit specific areas following well-known routes or trajectories.

Some nomadic herders exploit vertical ecological differences in pasture availability by grazing their animals in cooler and moister uplands during the summer months when grass and water are plentiful. By changing altitude from lowland to highland, nomadic herders avoid drought-prone lowland areas. In winter, nomadic herders migrate back to the lowlands to avoid the cold temperatures and snowfalls characteristic of the

highlands, and to find grass and water resources in familiar districts where their seasonal rights to resources are traditionally respected.

In lowland areas where large uplands are absent, nomadic herders spend their dry season grazing close to secure water resources, for example, a permanent stream or group-owned, hand-dug wells. A balance must be maintained between the water and grass available locally and the number of animals that the herders keep in a particular area. To prevent local overgrazing, lowland herders move away from their dry-season water sites during the wetter part of the year. This pulsating, horizontal movement takes lowland pastoralists far from their permanent base along a well-known trajectory to reach the areas that they know by experience are likely to have received rain or collected runoff. Nomadic lowland herders remain at these sites until grass and water are exhausted, and if additional resources are not located in the vicinity or the dry season is fast approaching, the herds are moved back to their dry-season water site.

Resource Rights

All nomadic herders claim the right to use grass and water to support their animals, but they assert absolute ownership rights over local resources only in critical areas. Usually, these exclusive claims are made by horizontal nomads to the grass and water needed to survive in the dry season and by vertical nomads to upland pastures with abundant grass and water. Often in these areas, the nomadic herders have dug the wells or have small agricultural plots to which they claim exclusive ownership. Along the routes they follow to seasonal pasture, nomadic herders claim the right to use unimproved, natural grazing as well as to draw water from local water sources. If the water comes from a well, or the pasture is a managed one, nomadic herders expect to pay a fee to the owner or government agency in control. If the area is wooded or controlled by a local tribal council, herders would expect to comply with local use regulations. Traditionally, nomadic pastoralists claimed the right to graze on the stubble that remained after crops were harvested. Farmers benefited from this grazing use,

Young Masai nomads with cattle in Southern Kenya

since the animals deposited manure and urea on the fields. These organic fertilizers were free, the farmer typically did not own enough animals to consume much of the postharvest residue, and poorer nomadic families often appeared soon enough in the harvest season to contribute useful temporary labor. Once beneficial to both farmers and herders, this dung-stubble connection has faded as a result of the modernization and mechanization of agriculture and the use of chemical fertilizers.

Herding Groups

Labor is a valuable commodity in pastoral communities, as is the political power needed to enforce pastoral rights. The need for labor is great because many nomadic herders keep several types of animals, each of which has a preference for specific fodder species. Camel herders,

such as the Kababish of Central Sudan and the Somali, may also keep sheep and goats. Because goat milk is an important part of the family diet, the goats are usually grazed near the family residence. Sheep are kept for their wool and their eventual sale in market centers. Sheep need high-quality grazing and daily water availability, so they often are herded separately in distant areas. Camels need far less water, can range far from the herder's domestic base, and can eat thorny, shrubby forage that most livestock reject. At different times of the year, each animal may be foraging far from other herd components, thus requiring separate herders for each species. To ensure enough labor to herd the animals of individual families, small herding groups are formed. These herding groups may contain up to a dozen families, depending on the time of year, and often have a core group of related males. If one family lacks young males to herd its animals, labor can be provided by others; if an unrelated elderly

couple lacks children, they can potentially remain in the group by herding for others. The composition of these groups is always somewhat dynamic; individuals enter and leave as their particular circumstances and comparative advantage permits and as disputes over the timing and direction of movements arise.

The camp group that herds and travels together is the basic building block of nomadic societies. Several herding groups compose a clan, several clans constitute a tribe, and several tribes can under charismatic leadership be grouped into a confederation. Through this hierarchical organization, the community's leaders exercise influence in pursuit of their personal aims and their tribesmen's goals. The ability to generate armed troops has made nomadic herders a formidable political force in many places such as Iran, Turkey, Saudi Arabia, and Mongolia. Herders have used their latent military potential to protect their resource use rights and the zones they deem critical from encroachment by rivals. The same force could be (and was) used to extract resources from farmers, merchants, and, on occasion, governments.

Pasture is owned by an entire community of nomadic herders, and every tribal member has the right to graze animals on the communal pastures controlled by the group. The group, represented by its leaders meeting in a tribal council, determines who can graze in an area and how many animals can exploit the area. People and groups not part of the community can maintain animals on communal pasture only if they have married into the tribe or if they have special political relations (often solidified by marriage) with tribal members. Maintaining such ties is primarily the responsibility of the leaders and is very important. Whenever a drought or a dispute with an enemy occurs, political connections are activated to provide alternative grazing opportunities or allies. Since many nomadic herders live in highly variable, low-productivity environments, these connections constitute an important safety net that offsets environmental and political hazards.

Environmental Management

Although herders use common pastures, herds are privately owned. This has led to claims that private exploitation of communal pasture always results in

overgrazing and, if allowed to proceed unchecked, to land degradation and desertification. This "tragedy of the commons" seldom arose under premodern nomadic herding conditions because herders were able to limit dry-season stocking ratios to the carrying capacity of an area. What human-imposed limits failed to achieve, nature ensured; rapid expansion of herds in a succession of good years was invariably offset by abrupt declines in herd numbers under prolonged drought conditions. This "boom and bust" rhythm was reflected in traditional nomadic pastoral systems. These herding regimes accepted the difficult, disequilibrium environments in which they had to operate and did not expect to produce a steady annual off-take from the range to sell in urban markets.

Modern governments, which depend on the political support of growing urban populations, favor a secure food supply that discourages urban riots and have promoted technological innovations that improve food security. Many of these development initiatives remove environmental constraints from nomadic herding. Wells that tap deep aquifers provide water in drought periods but concentrate so many animals that overgrazing occurs. Veterinary services improve the health of herds but keep too many animals on the range. Motor vehicles make access to pasture and market quicker but allow herds to reach distant grazing before regeneration from earlier use is complete. Herders are encouraged to settle (sedentarization) in order to access health and educational facilities, but pasture decline near settlements is common. Governments favor agriculture over herding by encouraging the conversion of prime grazing land into crop-producing areas and by converting dry-season grazing areas into irrigated agricultural zones. All these modern developments have the urban food consumer more in mind than the well-being of the nomadic animal herder. Only by modernized, mobile nomadic herding can many marginal zones remain contributors to human sustenance.

NOMADISM

Nomadism describes a pattern of human behavior for which mobility is essential. Nomadism is defined as continuous wandering, usually in search of food or sustenance. The popular image of the hobo, a homeless male of the late 19th and early 20th centuries, who jumped on and off freight trains while traveling the country looking for work probably comes as close to the basic definition as possible. A completely nomadic existence is almost never attained in reality. Nomadism seems more random in its spatial movement and organization to the outside observer than it is in reality to its practitioner. Most often, the term *nomad* is applied to animal herders, either as individuals or as groups, who move frequently and seasonally in search of support for the animals that form the basis of their livelihood.

Central to the classical concept of the nomad as an aimless wanderer is the belief that the nomad has no fixed home but rather moves where the spirit leads. The nomad is viewed as opportunistic in character, seizing opportunity whenever and wherever advantage exists. As soon as local conditions deteriorate or better opportunities are recognized or hoped for elsewhere, the nomad moves on to a new setting. In practice, mobile nomadic herders (pastoral nomads) are falsely regarded as aimless wanderers, lacking a permanent base, because they carry their home (a tent) with them and erect that dwelling whenever they stop. In practice, nomadic animal herders engage in regular movements between pasture zones that are only available at certain times of the year.

Movement enables these nomadic pastoralists to optimize pasture quality for their animals by shifting from poorer to better seasonally available pasture. Nomadic pastoralism is rotational grazing on a grand scale, substituting seasonal movements over hundreds of miles for the sedentary farmers' rotational shifts of livestock from paddock to paddock.

Nomadism is not migration, which is the process of shifting location from one place to another for a lengthy period. Many migrants have no intention of returning to their original home but rather plan (or hope) to remain permanently in the new location. The movement of European settlers to North America may have involved some returnees to their ancestral homeland, but the vast majority stayed at their destination. Nomadic peoples, for whom mobility is a dominant characteristic, intend to return to a base, usually a part of their total, exploitable habitat that is essential to their livelihood and sense of identity.

Many groups engage in livelihoods for which mobility is essential but are not nomads in the classic rootless sense. Duck herders in India traditionally traveled a regular, limited circuit from their bases in Tamil Nadu. Improved roads, expanded paddy rice areas that provide more postharvest grazing, and access to trucks now permits the movement of thousands of ducks over hundreds of kilometers following the rice harvest. Farmers in the foothills of the Alps and other mountain ranges habitually have moved their cattle to upland meadows for the summer, a seasonal oscillation called *transhumance*. Hunters and gatherers moved in synchronization with seasonal salmon spawning runs in the Pacific Northwest, as did wild rice harvesters in the Great Lakes. Nomadic herders, such as the Saami (Lapps) in Northern Scandinavia, continue to move their reindeer herds to mountain pastures each year. In reality, the idealized, aimless nomad is an idealized construct, viewed from the perspective of the permanently settled community and almost never realized in the real world, against which any more mobile group short of the ideal seems seminomadic.

NOMOTHETIC

Beginning with Schaeffer's (1953) famous attack on what he called *exceptionalism*, the claim central of the idiographic approach that history and geography are only concerned with the unique aspects of individual places, the discipline began a transition into a nomothetic body of knowledge,

one that sought general laws of explanation independent of time and space. Whereas idiographic understanding sought to uncover all the aspects of one place, nomothetic understanding sought to reveal how one phenomenon varied among many places.

The idiographic-nomothetic debate, also known as the *systematic versus regional geography* debate, raged throughout the 1950s and early 1960s. This clash of views essentially involved the question whether geography should be involved in general laws of understanding, that is, the relative emphasis on regional differences versus regional similarities, the factors that differentiated places or the commonalities that ran through them. Thus, the shift from an idiographic to nomothetic geography was closely (but not exclusively) associated with the broader decline in the regional approach. This move involved the triumph of the abstract over the concrete, the general over the particular,

and the universal over the specific. Nomothetic approaches valued abstraction and empirical regularities and held that the empirical world existed solely for the purpose of testing theory.

Rejecting the empiricism of the idiographic approach, nomothetic forms of geography are long associated with the attempt to make the discipline more “scientific” in the same sense as the physical sciences. Advocates of the nomothetic approach thus exhibited a disdain for induction and a sustained concern for the role of theory and explanation. This view centered on a sharp fact-value distinction, rigorous methods of data collection and sampling, deductive (also called *nomological*) logic, hypothesis testing, quantitative methods, reproducible results, and predictive ability. These tools are held to uncover the logical structures that underpin the play of empirical surface appearances. All these were hallmarks of the philosophy of logical positivism. In this account, the process of explanation involves embedding the unique within the general, that is, showing an individual set of observations to be the outcome of wider principles at work in a variety of places. A law is held to be a hypothesis that is repeatedly confirmed under controlled conditions. Choosing among competing laws involves invoking the principle of Occam’s razor, that is, choosing the simplest approach whenever possible. Methodologically, nomothetic approaches were closely associated with the rise of statistics and mathematical models, which were central to the rise of spatial analysis and location theory. Epistemologically, nomothetic views relied on a Kantian view of absolute space rather than later relativist notions of space as socially constructed.

Critics argued that this approach effectively reduced geography to geometry, ignoring historical context, social relations, or the role of human consciousness. Moreover, not all regional details could be so easily swept under the carpet of general theory, as the revived localities school maintained.

NONGOVERNMENTAL ORGANIZATIONS (NGOs)

Nongovernmental organizations (NGOs) are nonprofit associations that function independently of institutionalized government structures. NGOs are major players on the global stage because of their numbers and the extensive reach of their activities, often in remote areas with populations overlooked by the state and other organizations. For these reasons, it is important to understand the breadth of NGO activities, explore their history, and be familiar with the praise and criticism directed at these powerful organizations. Although they are grouped under a single, broad description, individual NGOs vary greatly with respect to their objectives, approach, culture, and scale at which they work. NGOs are influenced by the context where they work; their approach and capability vary greatly from place to place.

NGOs have a wide variety of objectives. They usually embrace political (e.g., democracy building), environmental (e.g., forest conservation, animal rights), or social (e.g., women’s empowerment) goals. They also often provide services to communities (e.g., drought relief). NGOs are active in the arenas of national and international politics, humanitarian assistance, and economic development. Some NGOs are staffed by volunteers, but NGO work has also gained prestige as a legitimate, and occasionally well-paid, career.

NGOs engage in a wide range of activities, including human rights advocacy, peacemaking, education and information dissemination,

democracy training and political participation of citizens, sustainable development, environmental conservation, capacity building and community organizing, social movements, law and advocacy, citizens' rights, research, training, provision of basic needs and services, community service, lobbying, and civil disobedience.

NGOs work at local, national, and international scales. They range in size from very small in terms of funding, geographic focus, and constituency to very large, with extensive funding, having geographically dispersed activities, and serving thousands of people. Regardless of the scale of their work, almost all NGOs are motivated by political or charitable ideals. Those NGOs motivated by charitable ideals seek to assist the neediest sections of society. NGOs motivated by political ideals strive to change society and remedy existing inequality. Most NGOs claim to act on behalf of the disenfranchised in today's globalized world. By siding with marginalized groups (e.g., women, slum residents, untouchables), they claim to speak for those who would not otherwise be heard.

Recent History of NGOs

In the 1980s, as development aid began to expand, NGOs were increasingly seen as groups that could facilitate flows of financial aid and services to the poor at a local scale. Because these organizations were already on the ground, locally connected, and in touch with the needs of their constituents, they were considered the ideal way to transfer development aid, technology, and services. International donors found NGOs ready and willing partners, engaged with the local communities that foreign aid was meant to reach. NGOs, for their part, often spent a lot of time looking for financial support, so the opportunity of capturing larger projects and a steadier source of funding from international donors was always welcome. Both a steady income stream and greater amounts of funding from abroad have enabled the growth of the NGO sector as a career in many developing countries.

Current estimates of the number of NGOs stand between 40,000 and the 100,000s—depending on how broadly the term *NGO* is defined. Only

100 years ago, the number of NGOs was estimated to be less than 200. The number, scope, and size of NGOs have proliferated in recent decades. The term *NGO* has become synonymous with any organization implementing economic or social development projects, especially those funded by foreign financial aid. The high-profile delivery of development aid and humanitarian services after a major natural disaster usually arrives through the efforts of NGOs.

The sheer variety of NGOs has led to attempts to categorize them based on the kind of work that an organization does, who it serves, at what scale it works, or from where it receives its funding. This has led to a proliferation of acronyms trying to capture all the different types of NGOs, but very few of these have come into common usage. There are simply too many types of NGOs, so the catchall term *NGO* continues to be favored. However, two useful distinctions have emerged that help separate large, global NGOs from small, local ones: international NGOs (INGOs) and community-based organizations (CBOs), respectively. INGOs are NGOs who have national offices in multiple countries, for example, CARE International. INGOs are distinctive for their global connectedness and large budgets. CBOs are locally based and usually locally funded groups with very strong links and responsibilities to their constituency; their membership comprises the community they serve. They are sometimes called *grassroots organizations*, because the group arose spontaneously from the “roots” of the community, usually in response to an intolerable political situation or environmental threat. CBOs are observed to have a different character from other NGOs because they are started and funded by communities seeking organized social and/or environmental change on a small scale or in a localized area.

In recent decades, NGOs have begun to form transnational networks, in which the resources and information of many different organizations, working at different scales and in geographically dispersed locations, are shared globally for the good of all. These networks have played important roles in disrupting global economic conferences (e.g., protesting meetings of the World Trade Organization) and supporting others (e.g., creating solidarity among women's groups at the United Nations conferences for women). They

also distribute research materials and other vital information from resource-rich areas of the world to resource-poor areas, and vice versa. NGOs are firmly embedded in a globalizing world, and they use their transnational networks like any other multinational organization would—to the greatest possible advantage of their goals.

Praise and Criticism

NGOs are now the preferred choice of donor organizations (sometimes themselves NGOs) for the delivery and provision of development aid and services. NGOs are ideally positioned to reach needy communities because of their history of working closely with such populations. Donors want to tap their local knowledge and field experience in out-of-the-way places. However, as aid from foreign sources to NGOs operating in poor countries has increased, donors have discovered the need to train NGO staff to carry out reporting and accounting procedures, as well as to increase their outreach skills, education, and strategies in the field or in the communities where they work. Donors have realized that NGO staff do not have the necessary skills to carry out the terms of their contracts.

A frequent concern for those watching NGOs is the question of NGO accountability. If NGOs are responsible for their constituencies, then the following question arises: “How are these communities to verify the funding and activities, mandates and reporting, of the NGOs that claim to serve them?” When the members of NGO constituencies come from poor and disenfranchised sections of society, it appears unlikely that they will have the political power to demand that NGOs remain accountable to them. On the other hand, as funding increases, donors financing NGOs want to track their money and report that the aid money is achieving results and improving the capacity of NGOs to deliver in the future.

Critics fear that the professionalizing activities demanded by donor agencies have shifted the focus of NGOs away from the people they serve toward meeting the demands and their responsibilities to donors. Increased reporting and monitoring, demands for efficiency and high-quality communication skills, and hierarchical salary

structures inside organizations have led to a shift in NGOs’ accountability away from their clients and toward their donors. Time and energy previously spent with clients becomes refocused on submitting the required documentation that will sustain funding. Instead of finding motivation in client-driven concerns, NGOs find their objectives driven by donor concerns to maintain funding flows. As donors place greater burdens of accountability on NGOs, NGOs may find themselves shying away from their political and social justice goals of facilitating greater access to economic and democratic opportunities for marginalized peoples.

It has been suggested that NGOs form a “third sector,” that is, neither a state enterprise nor a for-profit corporation. This position gives NGOs a perspective the other two sectors cannot provide. NGOs are not driven by profit, so social, political, and environmental goals can come first. NGOs provide a balance to the state, including the possibility of a challenge to state practices that may not be meeting the needs of citizens. Often, NGOs cast themselves in roles oppositional to a state that is ineffective, unresponsive to citizen needs, or not democratically elected. NGOs have played a significant role in creating and sustaining social movements.

But as NGOs have grown in size, scope, and number, concerns have been raised about whether or not NGOs can continue the work that led to their tremendous popularity, and what new roles they should or should not take on. The growing power of NGOs has led to fears that NGOs may come to replace the state and the services it provides. For example, instead of forcing the state to provide essential services (garbage collection, education, welfare), NGOs begin providing these services. The state withdraws from the social sector, passing on its responsibilities to NGOs and the donors that fund them. The problems with NGOs assuming these responsibilities say NGO critics is that NGOs are not accountable to citizens in the same way that the state is, nor is it appropriate for NGOs to assume service-providing roles over activist roles. Critics charge that NGOs have become apolitical service providers and encourage their constituency to take up responsibilities that enable the state to abnegate its role in providing for citizens.

NGOs have been criticized for moving away from their original, politically charged goals toward more politically neutral positions. They have been accused of seeking closer relationships with governments, instead of keeping watch on those in power and their policies. Some activists fear that without the leadership of NGOs, grass-roots political activism will disappear and voices against the status quo will be silenced.

Questions have been asked about the growing power and role of NGOs in governance at national and international scales. Some question the legitimacy of NGOs in international negotiations, such as their places at the table in venues such as the World Water Forum or the United Nations conferences on women. It is not clear what role NGOs should have in such meetings. NGOs are invited to the table in international discussions because they claim to speak for their constituencies at that local scale, but NGOs operating globally may find themselves cut off from their community-based constituencies. NGOs are not geographically sovereign, have little enforcement power, and no clear mandate to act as representatives. Those who would like to see NGOs representing civil society in international discussions fear that formalizing their participation might serve to limit the contributions NGOs make to global decision making.

NONPOINT SOURCES OF POLLUTION

A nonpoint source (NPS) of pollution is defined as any water pollution coming from a diffused source. Whereas point pollution sources such as wastewater from sewage or industries are discharged on a single location, NPSs can spread over a very large area where rain, irrigation, or snowmelt can carry pollutants and discharge them in streams, lakes, reservoirs, or coastal waters. These pollutants can be carried either over the ground through surface runoff or below the ground surface through seepage. Depending on their type, these pollutants can be carried over large distances and have a drastic effect on water quality.

Common NPSs

There can be many different kinds of NPSs, but the most significant are crop and grazing agriculture practices that use large amounts of insecticides and fertilizers. Fertilizers are chemicals usually containing nitrogen and phosphorus that are good plant nutrients. Although their presence in the water is not in itself a threat to human health, they encourage algae blooms and eutrophication of the water causing the death of fish and other life forms of the aquatic ecosystem. Both intensive and extensive domestic livestock produce huge amounts of feces that, when improperly managed, can pollute water and create a health

hazard for humans and other animals. Pathogenic diseases such as cholera, dysentery, and hepatitis A are known to be associated with the presence of feces in the water. Fecal coliform bacteria is a good indicator of the presence of fecal material in the water but should not entirely be attributed to feces. Storm runoff water from urban areas can escape the sewage system and carry toxic oils and chemicals to nearby streams. Bad soil conservation practices in agricultural areas can also promote soil erosion and increase the amount of sediment load carried by runoff to water bodies.

Controlling NPSs

Because many human activities are potential contributors, NPSs are inherently difficult to control. Although some of these activities such as burying toxic waste are illegal, others, such as spraying fertilizers and insecticides, are not only legal but are often encouraged and even subsidized by the government. This makes NPS pollution extremely hard to reduce on a large scale, and local policies seldom show sensibility or awareness of the problem. It is considered in many parts of the world as the leading source of water-quality problems. While many actions to reduce NPS pollution necessitate state action, such as the creation and enforcement of more restrictive laws of land management, other measures require local initiatives, such as the implementation of better soil conservation practices or the restoration of riparian vegetation, that can have a strong filtering effect on runoff water.

NONRENEWABLE RESOURCES

Humans use a variety of resources whose regeneration rates are too slow to show sufficient increases in stock sizes to be relevant to decision making. Examples include many of the energy sources on which modern economies depend, such as crude oil, natural gas, coal, and uranium, as well as many of the minerals and metals stocks that enter the economy—from iron and copper ores to gravel and sands, to trace minerals important in agriculture and many industrial processes. Other resources could, in principle, be considered renewable—such as tropical forests or fish populations—but current harvest rates are too high to allow for significant regeneration.

Optimal Extraction of Nonrenewable Resources

Given their finiteness, how much of a nonrenewable resource should be used at any given point in time? The 20th-century economists Lewis Gray and Harold Hotelling were the first to recognize that the conditions for optimal resource depletion are different from the optimality conditions for the production of ordinary goods. A basic assumption is that a nonrenewable resource can be extracted just once. Therefore, optimal prices of a unit of a resource must not only reflect its cost of extraction but also account for the opportunity costs associated with depleting the resource endowment by that unit. Traditional

economic models employ positive discount rates to reflect the possibility that technological improvement can give rise to increasing economic wealth and that even though future generations will inherit smaller *physical* resource endowments, an enlarged stock of human-made resources may compensate for the reduction in the physical resource base.

Challenges for Optimal Resource Extraction Models

Three major issues surround the formulation and application of models of optimal resource extraction: (1) discounting, (2) empirical applicability, and (3) the nature of partial equilibrium analysis of resource use.

Discounting

The choice of the discount rate is vital to the evaluation of economic activities since the discount rate determines whether an action has positive present value of profits or utility, whether it is better than others (has higher present value of profits or utility in the set of possible actions), and whether its timing is optimal (e.g., whether waiting would resolve uncertainty and thus increase present value of profits or utility).

Positive discount rates imply that consumption and production of future periods are valued less than present consumption and production. Once a discount rate has been chosen for evaluating alternative consumption and production plans, the question is whether this rate should remain constant over time. A constant discount rate is appropriate if economic agents assume that the probability of factors affecting the choice among actions remains constant over time. Since the determination of a social discount rate is controversial among economists, assumptions on the rate of change in the discount rate are unlikely to be accepted with consensus.

Empirical Relevance

Although traditional models of optimal extraction of nonrenewable resources are widely accepted among resource economists, empirical

evidence for them on the basis of firms' behaviors is rare and usually disappointing. Despite unreliable data, the lack of empirical support is partly because most models do not explicitly account for a firm's production capacities, capital requirements, capital utilization, and time adjustments in production technologies.

Traditional models of optimal nonrenewable resource extraction are also simplistic with respect to the behavioral assumptions on which they are built. For instance, short- and long-term decisions are typically not distinguished. Decision makers may not attempt to identify optimal extraction paths over potentially many decades to centuries but rather choose two or more sets of time periods over which decisions are made. As a consequence, one discount rate may be applied over decisions in the immediate future, while different discount rates may be chosen for the medium- to long-term periods.

Grey and Hotelling-style models on a macroeconomic level are more abundant than their microeconomic counterparts. With these models, time paths of various scarcity measures are investigated on an economy-wide basis. Potential candidates for economic measures of scarcity include resource prices, marginal extraction cost, or scarcity rent rates.

Partial Equilibrium Approach

By its nature, economic theory is anthropocentric and, thus, selective in the consideration of effects of economic actions on the environment and the role of environmental goods and services for economic activities. Many important environmental constraints are typically not captured fully in the economic decision process. Rather, these constraints are captured only as far as they impose apparent, immediate restriction on the deployment of the economically valued factors of production. A variety of constraints that are associated with unpriced material and energy flows that may lead to fundamental changes in the physical or biotic environment are frequently not, but in principle can be, considered. An example that has received considerable attention is climate change, which is being induced in part by the emissions of greenhouse gases from combustion of fossil fuels, methane

and carbon emissions resulting from land use changes, and reduced carbon sequestration from biomass harvesting.

History and Potential Future of Models of Optimal Resource Extraction

The debate about sustainability forces decision makers to broaden their view of the roles of nonrenewable resources and to compare alternative actions with respect to their long-term and systemwide costs and benefits. Use of nonrenewable resources may be considered optimal not only with respect to the narrowly defined partial-equilibrium criteria of traditional economic models of resource use but also with respect to issues concerning the long-term and large-scale performance of an economy that is an integral part of a changing ecosystem. To arrive at that systems view requires enriching traditional economic analysis with insights from physics (most notable the laws of thermodynamics) and ecology (e.g., the notion of material cycles, homeostasis, and evolution) to capture the long-term effects of nonrenewable resource extraction and use on economic and ecosystem performance, since many of the deciding attributes and impacts are not priced and thus not an explicit part of typical economic decision making. Conversely, disregarding these systemwide performance criteria may result in nonrenewable resource extraction at rates that leave the economy less sustainable, even though they may be “optimal” in the narrow sense of traditional resource economics. Reconciling the two perspectives is an active area of research and topic of continued consternation in public policy.

NONREPRESENTATIONAL THEORY

Nonrepresentational theory (NRT) is a reaction against the stranglehold of representation in cultural geographies. Although by no means unified, NRT in human geography has two broad positions. Epistemologically, it seeks to challenge the notion that representation is “all there really is” by emphasizing the unruly forces of life that elude cognitions and conceptualizations. It is in this sense that NRT does not herald the overturning of representation—perhaps, as Hayden Lorimer suggests, a better name for nonrepresentational theory would be “more-than-representational theory.” Ontologically, NRT breaks with a Cartesian division between “subject” and “object.” Replacing this philosophical dualism is a flat ontology based on the interplay of affect, practice, and performance. The work of Gilles Deleuze, a 20th-century poststructuralist philosopher, greatly influenced the general contours of NRT. Playing down the hegemony of “images of thought” and structural thinking in philosophy, Deleuze was keen to affirm a world where differences could roam free without being subsumed to representation. The *virtual* is the name Deleuze gives to the domain of differences, relationalities, and potentialities always latent within the world of actualized phenomena. The Deleuzian legacy is clear in NRT—cartographies of the virtual are already always “interfering” with our clearly

cut mappings of the world. NRT champions difference, immanence, and relationality over a geography based on repetition, transcendence, and division.

As the pioneer of NRT, the British geographer Nigel Thrift argues that NRT is at its core a “non-cognitive methodology” for being in the world. Similarly, Dewsbury believes that NRT is a way of presenting the world in all its immanence rather than *representing* it. That is, Dewsbury believes in a kind of “witnessing” of the world before it becomes discursively constituted through representation. In other words, witnessing is an experiential engagement with the radical relationality of perspective. Similarly, John Wylie’s work on landscape calls the reader into a postphenomenological reading of “being.” That is, his account of landscape does not denote a “gazed-upon” space by an intentional subject—landscape is rather the processual forces of being that disclose both subject and object. As a constant producing, landscape is none other than a Deleuzian *folding*. The subject is a folding of landscape itself, or rather, the subject is what comes to occupy the position of the fold—with difference created and assembled through the “variations” and “inflections” of folding. Landscape is thus the materialities and sensibilities *with* which we see. The Cartesian subject dissolves into endless foldings and texturings.

In summary, a nonrepresentational geography seeks to uncover the processual forces of our world that *produce* social and spatial relationships. This is achieved by a noncognitive methodology that pays attention to practice and performance. In a very Heideggerian sense then, NRT pivots around the central ontological condition of “being-in-the-world.” How do we relate with the world, with other humans, and with the nonhuman? NRT answers these questions from a variety of perspectives of philosophers from Maurice Merleau-Ponty and Martin Heidegger to Judith Butler and Bruno Latour. Interested readers should consult the works of geographers such as Nigel Thrift, J. D. Dewsbury, Derek McCormack, and John Wylie.

NONVISUAL GEOGRAPHIES

The interpretation of nonvisual landscapes explores the role of sensory and perceptual modes other than vision in the construction of geographic space. This topic positions itself at the boundary between social theory and behavioral geography by examining the ways in which nonvisual modes of information acquisition and processing reflect geographic environments and in turn shape those same places by structuring the subjective understanding and behavior of people and their symbolic understanding of space. This understanding and representation of geographic space emanates from several diverse conceptual perspectives, including behavioral geography and poststructuralism. At the individual level, we gather information in an environment from all our senses other than vision alone—hearing, smell, taste, and touch, which includes kinesthesia (muscle memory). Our spatial behavior is informed by these other sense modalities facilitating an understanding of space and place.

A vast array of information informs, guides, and shapes our understanding or misunderstanding about a place. The social construction of vision is dominant and is a historically contextualized way of knowing, also known as *ocularcentrism*. By delving into what vision is not, this line of

thought sheds new light on the role of vision in the making of place and spatial behavior.

Geography has long been emphatically ocular-centric, privileging the visual as a means to acquiring and representing spatial knowledge. Behavioral geographers note the fundamental role of vision in the acquisition of environmental information. A large body of work concerned with representations of space, ranging from cartography to GIS, has illustrated the complex ways in which graphical knowledge is related to visual perception. Many authors have noted the dominance of vision in human understanding, both at an individual behavioral level and at a social-cultural one. Vision is a metaphor for the ways in which we symbolically appropriate the world; for example, we often say “I see” for “I understand.” From Kant onward, the *cogito* of Western knowledge obtained objectivity (even if only mythically) by seeing everything.

The hegemony of vision—the unquestioned naturalness of sight—has come recently under mounting attack from diverse quarters. The changing role of vision in the late 19th century, as the experience of space and time was subjected to massive compression through photography, the telephone, and the automobile. More recently, geography has witnessed a remarkable convergence in social theory and cognitive-behavioral studies around this topic; increasingly, researchers in both of these domains have delved into the social construction of perception.

As a result, the “natural” dominance of vision has been undermined, and its hegemony has been shown to be a historical product. The linkages between ocularcentrism and modernity have been explored and have uncovered the masculinism of the “gaze” that sees all—and thus knows all. Building on Habermas’s theory of communicative interaction, Rorty argued that it holds that the proper model of knowledge is not the mimetic mirror but the conversation. The shift from visual to aural metaphors reflects the hegemony of post-positivist modes of understanding and the corresponding emphasis on knowledge as a multivocal dialogue. Critical social theorists like Lefebvre have argued that visual knowledge is grounded in its historical and political context and that every way of knowing is simultaneously a way of interacting, reproducing, or challenging social structures that are

intimately embedded in individual ways of comprehending the world. Academics teaching geography have reflexively questioned activities that require vision, such as field trips, computer-based spatial learning, and viewing PowerPoint slides. The analysis of geographic representation has been extended to the world scale, where visibility is a consistent theme. Vision, in short, is a political phenomenon as much as a behavioral one.

However, debates about the role of vision have also raised questions about the complex ways in which nonvisual information is key to the acquisition of spatial information and its representation. Much, if not most, interpersonal interaction is nonvisual, such as speech compared with body language; try having a conversation with your eyes closed and note the difference. As the body has become an inspirational topic of inquiry, the role of both visual and nonvisual perception in the construction of body space has received more attention. The spatial behavior of vision-impaired populations offers another means to appreciate the role of nonvisual systems of geographic information acquisition and processing. Although landscapes are primarily apprehended through sight, they inevitably are also known through other modalities. Nonvisual geographies (both tangible and symbolic) are largely unexplored and are apt to be unique in their own right. Phenomenologically inclined geographers such as Tuan and Porteous have been the most receptive to this idea, writing of “smellscape” and “soundscapes.” There is also a growing literature concerned with music, oral traditions, and audible text to describe landscapes in a different manner. Technology is emerging to embed listeners within virtual soundscapes, and for more than 15 years, conferences have run on the auditory display of spatial information. Even food and taste have become subject to geographic scrutiny. In short, to appreciate the importance of vision both literally and figuratively, it is essential to appreciate the significance of nonvisual ways of understanding. This is becoming ever more important with the acceleration of digital telecommunications facilitating nonvisual communication within cyberspace and to provide universal access to these technologies independent of vision, location, or technology platform.

procedures for defining rules of origin, expedited customs clearance for cross-border trade, and provided for a wide variety of institutional reforms to safeguard environmental interests and the rights of workers (sidebar agreements). The accord also included provisions to maintain stable flows of energy products, easier business travel, and reduced restrictions on foreign direct investment (FDI) across major sectors outside the energy domain (a concession to Mexico's oil industry). Despite many side agreements covering spheres such as labor conditions and environmental protection, a central goal of the accord was to achieve a phased elimination of import duties for most products and services by 2004. This goal has been achieved, though many nontariff trade barriers are still in place. A further goal was to dilute long-standing restrictions on capital mobility (FDI) and pave the way for new investment across the trilateral region. The net result over the past 15 years has been a dramatic expansion of intra-industry trade (IIT) between the three nations, with much of this IIT being conducted on an intracorporate basis.

Merchandise trade within the NAFTA area is now more than 70% IIT in nature. For example, Ford USA can import components or final assemblies on a duty-free basis from its subsidiaries located in Canada or Mexico—provided that such inputs qualify as 50% North American (i.e., “local content”). Automotive companies from outside NAFTA can also compete on the same basis, provided that 50% NAFTA content can be demonstrated. Since 1994, IIT within the trilateral partnership has witnessed explosive growth. Transnational corporations headquartered outside the NAFTA zone have played an important role too, especially in sectors such as automotive products, aerospace, and electronics.

From the perspective of classical or traditional trade theory, the NAFTA concept made good sense in 1994. With respect to relative factor proportions (comparative advantage), Mexico was cast as labor abundant (low skills), Canada had lots of natural resources, while the United States was capital rich (with high labor skills). Linking the three economies together via free trade would theoretically allow for factor specialization, expanded output, and an aggregate

NORTH AMERICAN FREE TRADE AGREEMENT (NAFTA)

The North American Free Trade Agreement (NAFTA) was ratified in 1994, linking Canada, Mexico, and the United States under a regime of liberalized trilateral commerce that harmonized

About 200 teamsters raise their signs while protesting new NAFTA trucking regulations outside the Holiday Inn in San Diego, June 18, 1996. The teamsters protested a meeting on the North American Free Trade Agreement against lifting a ban on Mexican trucks being allowed on U.S. roads and highways.

rise in consumer welfare. Specialization would also promote economies of scale (increasing returns), a core tenet of new trade theory. Critics of the accord, in contrast, argued that a free trade agreement between two advanced industrial economies and a developing nation within a geographically contiguous region would spur a mass exodus of capital from north to south, as well as downward pressure on northern wages. Neither perspective appears to be entirely correct.

The World Trade Organization (WTO) does not view bilateral or multilateral free trade agreements in a favorable light because such agreements violate core principles such as nondiscrimination and/or most-favored-nation status—principles that were developed and negotiated under several

decades of painful deliberations among hundreds of nations under the General Agreement on Trade and Tariffs. The WTO was proposed as a model for free trade at the global level but tolerates regional agreements provided that they do not cause trade diversion. Thus far, there is no evidence that NAFTA has caused trade diversion to any significant degree. Trade diversion takes place when a regional free trade agreement artificially displaces a lower-cost producer from outside the club as a result of policy-driven cost advantages that accrue to in-club producers. NAFTA does not seem to be a factor in this regard, as witnessed by the massive imports from China, India, and other low-cost producers located in the newly industrializing countries of Asia and South America.

Thus far, econometric modeling has failed to uncover significant evidence of trade diversion (most models are suggestive of trade expansion). Recent econometric work also points to either a zero or negligible impact of NAFTA on U.S. industrial employment. Some studies, in fact, suggest that NAFTA's tariff reductions have decelerated the pre-NAFTA trend toward employment decay in the manufacturing sectors of both Canada and the United States. Between 1994 and 2000, for example, total employment in the U.S. manufacturing sector actually increased (albeit by a modest 1%). On a less optimistic note, there is at least some evidence that trade liberalization has contributed to rising income inequality between regions for all three NAFTA members.

This said, most economists and economic geographers would agree that it is hard to disentangle the trade, income, or employment effects of free trade agreements from broader factors such as capital intensification (process automation), exchange rate movements, import competition from outside the bloc, and declining industrial competitiveness (e.g., lack of investment in new technology). For example, some studies have found a negative relationship between NAFTA-assisted export growth and local employment levels. Capital intensification appears to be the key driver in this rather odd relationship.

Although NAFTA has been a topic of considerable debate over the past 15 years, the accord is here to stay. Looking to the future, at least five areas of contention are likely to persist and/or emerge. These areas of contention include the following:

1. The increasingly adversarial relationship between the United States and Mexico regarding illegal immigration
2. The persistence of nontariff trade barriers based on technical or environmental standards
3. The hardening of U.S. ports of entry in light of post-9/11 security threats
4. The management of NAFTA expansion (Free Trade Area of the Americas)
5. The development of more efficient border management systems

Some of these concerns might be addressed by moving toward a secure external perimeter, where the boundaries of all three nations are monitored and controlled by common standards to facilitate security compliance. This will probably not happen soon, as such a scenario would push NAFTA closer toward a customs union (which is not a politically popular option). Other concerns might be addressed by further policy harmonization, notably with regard to border management (e.g., fast-track entry for people and merchandise). Still other concerns might be dealt with by broadening the mandate of NAFTA's dispute resolution system to include issues such as illegal immigration, antiterrorism measures, and environmental compliance.

NORTH ATLANTIC TREATY ORGANIZATION (NATO)

The North Atlantic Treaty Organization, commonly known as NATO, is a mutual defense alliance founded on April 4, 1949. NATO's most basic principle is that its 26 member countries pledge to regard an attack on any one of the members as an attack on all members and respond

accordingly. In addition to responding after an attack, NATO also provides an organizational framework for joint military training, planning, and command and control during peacetime. By fostering a high degree of military cooperation and preparedness, NATO aims to deter external threats and advance the collective security of its members.

NATO was one of a number of supranational organizations established in Europe following World War II. Although varied in form and function, these international organizations helped facilitate Europe's postwar recovery by promoting economic and political cooperation. While the European Union and its predecessors focused mainly on economics, NATO emerged as the foremost organization related to military and security issues. As the Soviet Union tightened its control over much of Eastern Europe after 1945, the United States and its European allies began discussing ways to fend off possible Soviet advances into Western Europe. Comparatively small and still recovering from World War II, it appeared unlikely that these Western European countries, even if they joined together, could repulse an attack launched by the much larger Soviet Union.

As a result, NATO was established with the implicit purpose of deterring a Soviet attack by promising a direct American military response, including the possibility of nuclear retaliation. Although not specified in the actual text of the treaty, NATO was largely conceived as an American security guarantee to protect its European allies from the Soviet Union. The Soviet Union responded by arranging a similar military coalition, the Warsaw Pact, with the communist-controlled governments in Eastern Europe. These competing alliances, both backed by nuclear weapons, created a rough balance of power between the NATO military alliance in the west and the Warsaw Pact countries in the east. Given the high probability that any confrontation would escalate to nuclear war, neither side had much room to maneuver. Because of this stalemate, the situation is often referred to as the Cold War, marked by heightened geopolitical rivalry but lacking direct military engagements.

NATO's original roster consisted of 12 members: the United States, Canada, and 10 European

countries (Belgium, Denmark, France, Iceland, Italy, Luxembourg, the Netherlands, Norway, Portugal, and the United Kingdom) mostly along the Atlantic coast, hence the organization's name. By 1990, membership had expanded to include Germany (West Germany in 1955, which included East Germany in 1990), Greece, Spain, and Turkey. Although there were periodic disagreements among NATO members regarding military policy and relations among themselves and with the Soviet Union, the alliance is generally regarded as successful in deterring communist expansion and contributing to economic and political stability in Europe during the Cold War.

The collapse of the Soviet Union and its Warsaw Pact coalition in 1991 opened a period of uncertainty regarding NATO's future. Its rationale for existence, countering a Soviet offensive into Western Europe, was gone. Despite this, NATO has in many ways become more active in the post-Cold War period. First, NATO membership has increased dramatically to reach 28 members with the additions of Bulgaria, the Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland, Romania, Slovakia, and Slovenia in 2004 and the joining of Croatia and Albania in April 2009. The current governments of Macedonia, Ukraine, and Georgia have also expressed a desire to become members. These new and potential members, all communist countries during the Cold War, have been eager to join NATO and the European Union in the belief that membership will help counter any attempt by Russia to regain its former influence in Eastern Europe.

Second, although NATO originated as a limited defensive pact, it has become increasingly active in a mix of humanitarian and combat operations beyond the borders of its member countries. During the 1990s, NATO forces were active in parts of the former Yugoslavia. NATO's bombing campaigns against Serbian forces helped end the Bosnia civil war in 1995 and the ethnic cleansing in Kosovo in 1999. NATO-led peacekeeping forces were subsequently deployed in both areas.

The September 11, 2001, attacks against the United States marked an additional turning point for the alliance. Although originally conceived as a mechanism for the United States to assist its allies if they were attacked, the September 11 attacks prompted NATO to declare the attacks

Figure 1 NATO's 28 members in 2009 include the United States, Canada, most of Europe, and Turkey.

Source: Barney Warf.

by the al Qaeda/Taliban regime on the United States as an attack on all NATO members. As a result, NATO-led forces, exceeding 40,000 by 2008, have been active in counterinsurgency, humanitarian, and reconstruction efforts across Afghanistan.

Despite expanding in size and scope since the end of the Cold War, NATO's future remains uncertain. The alliance's contributions in Afghanistan have been criticized for inadequate manpower and resources. While all members have deployed some troops, several countries have specified that their troops not take part in combat operations. It remains unclear if NATO will truly be able to sustain an alliance-wide deployment or if a small group of NATO countries will effectively assume responsibility for all combat operations while most members restrict their troops to relatively peaceful parts of Afghanistan. A second source of concern for NATO is its relations with Russia. Given its origin as an anti-Soviet alliance, Russia's desire to halt NATO's continued expansion into Eastern Europe and former Soviet territories is understandable. Partly in response to heightened tensions over NATO's eastern expansion, Russian leaders have periodically warned that a new Cold War may develop. Indeed, despite

assurances from the United States and other countries that NATO is no longer directed against Russia, it is clear that some Eastern European countries regard NATO as a check against Russian influence. Although it has outlived its original purpose, it is unclear if NATO will assume a more global profile or largely confine itself to the North Atlantic area.

NOT IN MY BACKYARD (NIMBY)

“Not in My Backyard” is a common, if stereotyped, slogan of neighborhood and community groups opposed to locally unwanted land uses. Typically, NIMBY movements arise in opposition to perceived environmental threats such as toxic waste dumps, trash incinerators, recycling centers, or landfills; at the state level, they may oppose nuclear power plants or potential transportation routes for trucks or trains carrying dangerous chemicals. In the 19th century, urban locational conflicts erupted over the siting of slaughterhouses, rendering plants, and saloons. NIMBY alliances may arise against social (as opposed to environmental) categories of land uses they deem as undesirable, such as shopping malls, prisons, bridges or tunnels, low-income housing projects, transit systems, homeless shelters, drug rehabilitation centers, or halfway homes for mildly retarded people.

NIMBY movements reflect the spatial distribution of undesirable effects on people’s welfare, such as impingements on their health, noise, or fears of crime or visual and aesthetic blight (typical concerns of low-income NIMBY movements), or negative effects on their property values (a frequent motivator of middle-class ones). Other NIMBY arguments are that the unwanted land use will destroy a small town or neighborhood environment or strain local public resources. NIMBY tactics may include lawsuits, working the legislative and judicial machinery, protests and demonstrations, public relations campaigns in the media (e.g., letters to newspapers), and behind-the-scenes pressure on elected officials.

The strength of NIMBY movements varies in accordance with the socioeconomic status, educational level, and financial resources of its members. Low-income minorities generally have less access to political power in most municipalities, whereas white, middle-class communities are more likely to have the ear of city government officials and be better positioned to oppose unwanted land uses through the courts or bureaucracies. Because decision makers siting noxious land uses, that is, large real estate developers, are more likely to attempt to locate them in predominantly minority

and low-income areas, such communities are more likely to give rise to NIMBY movements, often under the banner of environmental justice. Because local issues affect people’s everyday lives, often in profound ways that speak to their deepest hopes and fears for their future quality of life, NIMBY movements can attract members who are otherwise usually disengaged from formal politics, such as housewives.

Critics of NIMBY movements maintain that they are elitist or parochial and that they hamper necessary development, exhibit a so-called draw-bridge mentality, or are covertly attempting to maintain neighborhood racial homogeneity under the banner of opposition to other unwanted aspects such as noise or pollution. Some argue that NIMBY movements are ethically inconsistent, simply attempting to displace unwanted land uses to less politically powerful areas—that is, they displace the problem rather than solving it. On this reading, NIMBY movements are irrational, selfish, misguided, and obstructionist, and by privileging local interests over social needs, they prevent the attainment of societal goals. After all, facilities such as waste incinerators must go *some-where*. Critics of NIMBYs thus maintain that they elevate local benefits over broader social ones.

A structuralist interpretation of NIMBYs points to the inequalities inherent between the production and consumption of urban space, particularly the spatial distribution of negative externalities in the forms of locally concentrated costs and dispersed social benefits. Rather than irrational opposition to land developers, local resistance is viewed by some as an inevitable outcome of the urban development process. NIMBYs represent consumers of land who are invested in a particular landscape under the threat of change, and their opposition to new facilities is a means of constraining the behavior of capitalists, who often enjoy the backing of the state. Thus, they can no more be annihilated than can private capital investments in the landscape, and they provide a necessary countervailing measure to land developers who would otherwise proceed unchecked.

NUCLEAR ENERGY

Images of the electric grid, cooling towers, atomic bombs, and Hollywood productions serve as examples of what may come to mind when “nuclear energy” is mentioned. It has a complex narrative, occupying a noteworthy place in society.

What nuclear energy represents to current debates on solutions to increasing energy demand, reduction in carbon emissions, energy independence, and national security is juxtaposed with arguments of nuclear proliferation, radioactive contamination, nuclear accidents, and “not in my backyard” sentiments. With a growing presence around the globe with 440-plus commercial reactors in operation or being built, an argument is being made that there is a 21st-century nuclear resurgence in the making. Nuclear energy engages the subatomic realm, natural landscapes, and geopolitical space in particular ways—an engineered solution to some and a problem to others.

The Subatomic

Nuclear energy, also known as atomic energy, occurs with the splitting of a specific atom. The sustained process is known as nuclear fission; heat released from the substance is harnessed to produce steam in commercial nuclear reactors.

Through a series of progressions, the work of the steam becomes electricity. The atom used in commercial nuclear power plants is uranium. This ore is crushed and leached with acid to obtain a concentrated amount of uranium oxide known as yellowcake. In nature, this isotope of uranium exists at low concentrations, typically 0.7%. So that it can be used in commercial reactors, it goes through an enrichment process, increasing its concentration to 4.0% to 5.0%. Pellets that include the enriched uranium are placed in fuel rods that, in turn, are configured into fuel assemblies to make up the reactor core. There are several reactor designs throughout the world; the two predominant designs in the United States are known as boiling water reactors and pressurized water reactors. The electricity produced in these and other commercial reactors is known as nuclear power. Nuclear energy and nuclear power are used interchangeably for the simplified representation of the splitting of atoms.

Nuclear energy can also be derived from joining the light nuclei of atoms with the heavier ones. Two isotopes of hydrogen are combined into helium; the energy released will be harnessed for eventual fusion reactor applications. At present, the mechanics of a fusion reactor is not complete for commercial applications; it is in the research realm—more energy is currently used for the reaction to occur than is released. National and international initiatives continue, the latest being a joint international research and development project, ITER, in Southern France.

Nuclear Politics

Scientists who played a key role in research that led to fission power production included the British nuclear pioneer Ernest Rutherford. He brought attention to the heat produced by the atom radium. French scientists Marie and Pierre Curie, along with Henri Becquerel, discovered radioactivity; the German American scientist J. Robert Oppenheimer is considered the father of the atomic bomb; and the Italian scientist Enrico Fermi discovered fission. From the work of these scientists on the atom has come the work of the atom on and for society.

Currently, research is under way to usher in the next generation of reactors; they are being

Nuclear power plant in Lower Saxony, Germany

Source: Hans F. Meier/iStockphoto.

designed to be modular in construction, to possess shorter building times, to have fewer pumps and valves, and to use less uranium to produce the desired level of energy. Idaho National Laboratory was named the lead laboratory by former President George W. Bush to shepherd the United States into the next stage of nuclear power production. Through the U.S. Energy Policy Act of 2005, initiatives for a nuclear renaissance are being constructed. Internationally, the resurgence is showing more traction; for instance, in 2004, Finland started construction on a next-generation Areva-designed nuclear reactor. Companies such as Areva, Westinghouse, and General Electric-Hitachi, in association with the governments of various countries, are building in Japan, China, and India. Discussions are under way in countries such as Mexico, Canada, and South Africa. The United States hasn't built a new commercial

nuclear reactor in decades, but there are several consortia (vendors such as companies named earlier along with state utility companies) that wish to take advantage of the tax credit incentives and liability insurance. They are submitting applications to the U.S. Nuclear Regulatory Commission for combined construction and operating licenses. The review process takes several years; however, there have been possible construction locations announced by utilities. For example, the North Carolina-based Progress Energy has named Florida and then North Carolina as build locations.

Geography of Fear, Geography of Necessity

Nuclear energy was ushered in as an offshoot of scientists' work on behalf of military defense. During World War II, the atomic bomb was used on Hiroshima and Nagasaki, Japan, as a response to

the Pearl Harbor bombings. An enrichment level closer to 90%, as opposed to the 4% to 5% range seen in commercial nuclear power plants, was used. This technological use solidified the nuclear arms race, and nations such as Britain, China, and the Soviet Union developed a military arsenal in the postwar, Cold War era. Other nations subsequently joined the nuclear race with more of a power production perspective. Japan, France, and South Africa were among these nations.

In 1953, the then U.S. President Dwight Eisenhower pledged before the United Nations the pursuit of nuclear science and technology for peaceful purposes. The U.S. Department of Energy and the U.S. Nuclear Regulatory Commission continue to work with industrial and public stakeholders to answer concerns and move forward on nuclear energy production. As of 2008, there were more than 443 nuclear reactors worldwide (representing 19.4% of the global nuclear power) and 104 nuclear reactors in the United States (19.9%); France represents 80% and Canada 12%. Nuclear power is used as base load—reactors run year-round, except when down for refueling and maintenance—contributing to guaranteed electricity for households and industry. According to the Department of Energy, U.S. electricity demand is expected to increase by 40% to 50% by 2025. And as industrialization occurs around the world, there will be an increased demand for fossil fuels, driving some of the discussions around energy independence and global warming reduction measures to include renewable and nuclear energies as possible solutions.

Similarly, in a post-9/11 world there has been concern expressed about nuclear terrorism—a hijacked plane crashing into a nuclear power plant or the use of stolen radioactive material to make a dirty bomb—not to mention the lingering historical references and/or concerns around another Chernobyl accident or Three Mile Island incident. What affects would a leakage have on communities near nuclear power plants? What evacuation plans are in place? What measures exist for the safe operation of nuclear power plants? Where should nuclear waste be stored? Military and industrial nuclear waste, slated to eventually reside at the Yucca Mountain National Repository in Nevada, is under litigation. The nuclear industry has launched public outreach initiatives to answer these and other questions. At

the same time, antinuclear organizations are engaging communities around issues of environmental justice, land rights, and safety practices. The geographical space of nuclear energy has been reenergized. The politics of engineered landscapes and their necessity plays out on several levels as demand places pressure on natural resources and a geography of necessity is amplified.

NUTRIENT CYCLES

Nutrient cycles describe the cycling in terrestrial, limnic, or marine ecosystems and in compartments of these ecosystems of those elements and chemical compounds that are essential for maintaining life. The essential elements include the macronutrients (nitrogen [N], potassium [K], calcium [Ca], magnesium [Mg], phosphorus [P], and sulfur [S])—ordered in the sequence of the mass contributions of these elements to dry shoot matter of higher plants according to Marschner, 1995) and the micronutrients (chlorine [Cl], boron [B], iron [Fe], manganese [Mn], zinc [Zn], copper [Cu], nickel [Ni], and molybdenum [Mo]). Some microorganisms, animals, and humans additionally require other elements such as chromium (Cr), selenium (Se), and

vanadium (V). Carbon and water, which are also needed by all living organisms, are usually not considered as nutrients. This entry focuses on nutrient cycles in terrestrial ecosystems.

Nutrient Cycles in Ecosystems

The cycling of nutrients can be studied at different scales from a few millimeters to the global scale. The most common scale at which nutrient cycling is studied is that of a small plot of 100 to 1,000 square meters or of a small catchment of a few hectares to square kilometers, which are considered as representative for a well-defined ecosystem or landscape. Ecosystem functioning is described by input fluxes, output fluxes, state, and transfer functions translating input into change of state and input and change of state into output. Methodologically, nutrient cycling in ecosystems is frequently assessed by budgeting nutrient stocks and fluxes.

Nutrient stocks are usually determined for different ecosystem compartments such as soil (various depth layers) and below- and aboveground biomass (sometimes further subdivided, e.g., into fine and coarse roots or stems, branches, and leaves) in terrestrial ecosystems.

Nutrient fluxes can be gaseous, water bound, or solid-phase associated. Gaseous fluxes include N_2 fixation from the atmosphere; deposition of nutrient-containing substances, such as ammonia (NH_3), oxides of nitrogen (NO_x), sulfur dioxide (SO_2), nitric acid (HNO_3), sulfuric acid (H_2SO_4), and hydrochloric acid (HCl); and volatilization of NO , N_2O , and N_2 via nitrification and denitrification. Water-bound fluxes include incident precipitation, throughfall (i.e., the part of incident precipitation that falls through the canopy and reaches the soil), stemflow (i.e., the part of incident precipitation that flows via branches and stems to the soil), surface flow (on top of soil), internal soil fluxes (vertical and lateral), stream, and groundwater flow. While water itself can evaporate (via interception, i.e., direct evaporation from the vegetation surface, transpiration through plants, or direct evaporation from soil and water bodies), the nutrients contained in water cannot. Solid-phase-associated fluxes include dry particulate deposition from the atmosphere, litter fall (including fine litter, coarse

litter, and root litter), soil erosion, and bedload and suspended matter in streams.

Nutrient Turnover

After biomass dies and returns as dead organic matter to soil, all contained nutrients are released via leaching and mineralization after mechanical degradation of the fresh litter by soil animals. Mineralization is particularly important for the nitrogen cycle (but to a lesser degree also for all other nutrients). Nitrogen mineralization consists of the release of ammonium (NH_4^+) from organic compounds ("ammonification") and the subsequent oxidation of ammonium to nitrate (NO_3^- , "nitrification") in several steps. Mineralization is a microbiologically mediated process. Mineralization rates depend on climatic conditions (temperature and water availability), chemical milieu (acidity and oxygen availability), and properties of the mineralized organic matter. Mineralization is fastest if the mineralizing microbial community experiences optimum conditions.

Nutrient Cycles in Forest Ecosystems

Perhaps the most studied ecosystems with respect to nutrient cycling are the forest ecosystems. Figure 1 summarizes the results of a study of the potassium cycling in the Brazilian Cerrado, where the native savanna vegetation was compared with nonnative *Pinus caribaea* Morelet plantations on similar soils in the Cerrado region. It becomes evident that nutrient fluxes are small compared with nutrient stocks, which is a general feature of forest ecosystems. The Cerrado case study, however, shows particularly small element fluxes—such as many tropical ecosystems—because the deeply weathered tropical soils are extremely nutrient poor. The native Cerrado vegetation and the pine plantation currently accumulate nutrients from the atmosphere, on balance. This is usually not the case in temperate forest ecosystems on less weathered soils from which nutrients may be net released and leached.

Methods for Assessing Nutrient Cycles

To assess nutrient stocks in the different ecosystem compartments, inventories of biomass and

soil mass and nutrient concentrations in the various compartments need to be undertaken. Usually, aliquots of the compartments are sampled and destructively analyzed. The aboveground water-bound fluxes can be directly measured with special containers collecting incident rainfall (usually measured in clearings or above the forest canopy), throughfall (for which many samplers are needed because throughfall is heterogeneous), and stemflow (the water running down the trunks that is collected with the help of a collar around the stem). In soil, either special lysimeters, which quantitatively collect the percolating water, are used (with high technical efforts and at the disadvantage of some unavoidable disturbances of soil and vegetation) or nonquantitative lysimeters (e.g., the suction cups or plates) are used to determine

nutrient concentrations in soil solution. Then, nutrient fluxes are calculated with the help of a soil water model providing the water fluxes. Furthermore, fine litter fall can be easily collected with litter traps, while the determination of coarse litter fall is more laborious requiring inventories of large pieces of dead organic matter on top of the soil, including standing dead trees. Dry deposition (fine particles and gases) from the atmosphere cannot be measured directly but usually is modeled with complex micrometeorological models or budget approaches of the vegetation canopy. Organic matter turnover can be measured in the field by various approaches (e.g., litter bags that are left on the soil for a certain time to allow for degradation) or in the laboratory by incubating at controlled temperature, moisture, and nutrient

conditions (usually yielding an optimum turnover rate above that in the field). A full nutrient-cycling model combines algorithms describing all fluxes and turnover processes in an ecosystem.

NYERGES, TIMOTHY (1951–)

Timothy L. Nyerges, professor of geography at the University of Washington, has published numerous influential works on schema integration for spatial databases, information structuring in the analytical use of maps, typologies of geographic information abstractions, the uses of

GIS in transportation planning, the prospect for public participation in GIS use, data-gathering strategies in the study of participatory GIS use, and the design of a Web-based PPGIS (Public Participation GIS).

Nyerges received his PhD from Ohio State University in 1980 under the supervision of Harold Moellering (known for research about animated, analytical cartography, and digital cartographic data standards) and Reginald Golledge (University of California, Santa Barbara, known for research in cognitive and behavioral geography). His dissertation, titled *Modeling the Structure of Cartographic Information for Query Processing*, represented innovative research in the structure of spatial data just as the GIS industry was taking off.

On finishing his PhD, Nyerges worked for 5 years as a computer-cartographer and GIS consultant, eventually moving to the Seattle area in 1983. While a consultant, he served as chair of the Technical Working Group on Data Organization, part of the National Committee for Digital Cartographic Data Standards, a position he held until 1987. He has remained an active advisor at the national level in the area of spatial data standards.

Since 1985, Nyerges has been a member of the faculty in the department of geography at the University of Washington in Seattle, where he has completed research in collaborative spatial decision support systems funded by the National Science Foundation, Environmental Protection Agency, and the Department of Energy. He has also shepherded the undergraduate and graduate GIScience curriculum and served on nearly 50 master's student committees and nearly 30 PhD student committees. He has also served as the director of the governing board for the university's Center for Social Science Computation and Research (1991–1996) and as a board member for the Program on Environment (2000–2003).

Nyerges is an affiliate faculty member at the Center for Water and Watershed Studies in the College of Forest Resources, in Civil and Environmental Engineering, and in the Interdisciplinary PhD Program in Urban Planning and Design. Nationally, he has served as the research chair and program organizer (2005–2008) for the

University Consortium of Geographic Information Science summer meetings and the 2005 Urban and Regional Information Systems Association's Public Participation GIS conference, and he is the 2009–2011 president of the University Consortium for Geographic Information Science.

Participating in the GIS and Society debates of the mid 1990s, with his involvement in the Friday Harbor, Washington, meetings, Nyerges has continued to advance a research agenda on the study of GIS use. His work with Piotr Jankowski (a former student of Nyerges) has led to the development of thorough research designs in the study of GIS use in group decision-making situations, what Nyerges and Jankowski termed *enhanced adaptive structuration theory*. Jankowski and Nyerges ground their thinking about social-behavioral research on spatial decision making, which framed later studies of GIS use for transportation, land use, and water resource decision making.

His recent research has included a 4-year NSF (National Science Foundation) project concerning participatory GIS for transportation, which funded more than 15 graduate students from 2003 to 2007 at the University of Washington, San Diego State University, and the University of Wyoming. The research team, with Nyerges as principal investigator, designed and implemented an Internet platform to support and study public participation in transportation decision making. Nyerges continues to extend this research in the development and study of Internet-based GIS in the area of community vulnerability to regional climate change and variability and coastal zone management.

OBJECT-BASED IMAGE ANALYSIS

Object-based image analysis (OBIA) is a new approach to the analysis of remote-sensing (RS) images in which the basic units, instead of being individual pixels, are image-objects. An image-object is a relatively uniform region of a digital image somewhat different from its surroundings. Typically, image-objects are initially delineated by a segmentation algorithm and then further aggregated using a semiautomated classification that takes into account both their internal features and their mutual relationships. OBIA aims to replicate visual interpretation through semiautomated means, providing greater integration with vector geographic information systems (GIS) with increased consistency and efficiency.

OBIA is an increasingly popular alternative to the traditional pixel-based approach to semiautomated thematic mapping using RS imagery. Pixel-based methods assume that different thematic classes behave like distinct surface materials susceptible of being analyzed with a spectrometric approach. That is, each pixel is treated as a sample introduced in a desktop spectrometer, where its spectral signature (represented by the different values the pixel takes in each band of the image) is compared with the ones of selected samples (training pixels) of each material that can be found in the to-be-mapped

territory. After comparison (i.e., classification), the material having the most similar signature(s) to the one under analysis is selected as the class to which that pixel belongs. The main drawback of this approach is that it cannot exploit the fact that pixels are knitted into an image full of spatial patterns.

In contrast, in OBIA, the spatial structure of the image is explicitly captured by the initial segmentation step, which creates a set of jointly exhaustive, mutually disjoint regions (image-objects) that are more uniform within themselves than when compared with adjacent regions according to a set of predefined similarity criteria. After segmentation, the values of a wide assortment of attributes (radiometric, textural, morphological, and relational) are computed for each image-object, which form the basis for classification. The latter typically consists of an iterative process, where the membership of particular image-objects to a given class may change according to the status of neighboring objects. During this process, image-objects may also be hierarchically nested to allow for the introduction of powerful contextual rules. For example, a group of nearby but not adjacent image-objects labeled “tree,” if surrounded by larger image-objects identified as “soil,” could be merged into an “orchard” superobject. If the latter happens to be in turn embedded in a “city” superobject, it could further change its membership to the “urban park” class.

It is important to note that OBIA encompasses techniques used in many disciplines other than geographic information science. To distinguish RS/GIS OBIA from other domains such as biomedical imaging, the acronym GEOBIA (Geographic Object-Based Image Analysis) has been recently proposed, although it is still unclear whether this acronym will become widely used.

OCEANIC CIRCULATION

Oceanic circulation is responsible for the majority of heat transfer within the Earth system and, hence, determines weather and climate for the majority of humankind (Figure 1). Circulation within the ocean is patterned by numerous forces but mostly reflects spatial differences in density and heat that are in turn minimized by a complex system of currents within the major ocean basins. The forces affecting ocean circulation are thermohaline differences (horizontal and vertical variations in salt concentrations and temperature), surface-wind-generated stress, the Coriolis force (the deflection of moving bodies across the Earth surface due to its rotation), and underwater topography. This entry will discuss the resulting circulation pattern below, which demonstrates the spatial relations between centers of high and low pressure, the gyres these systems create, as well as the warm (*red*) and cool (*blue*) surface currents that result from interactions between these rotating systems and the larger scale thermohaline circulation.

The major forces driving oceanic circulation are best illustrated by the various gyres (rotating systems of low- or high-pressure-generating wind and water currents) of the ocean basins and the large-scale oscillations associated with El Niño and the monsoonal cycle of the Indian Ocean. Each example highlights the complex interaction of atmospheric pressure systems with the ocean surface and the role of the various forces mentioned above that interact to produce the patterns of oceanic circulation. The most fundamental of these forces, however, is thermohaline circulation.

Thermohaline Circulation

Compared with the circulation patterns generated by atmosphere-ocean coupling and the Coriolis force, thermohaline circulation is extremely slow, on the order of millimeters per second (mm/s), compared with wind-driven current systems (centimeters per second [cm/s]). Despite its slow pace, thermohaline circulation results in a horizontal range of temperature nearly matching the vertical gradient (30 to -1 °C). For the vertical gradient, this results in two distinct zones: (1) the mixed layer (generally the upper 50–200 m [meters] depending on latitude) in which temperatures approximate the surface, and (2) the thermocline (200–800 m in tropics, 50–100 m in summer midlatitudes, nonexistent in polar latitudes and winter midlatitudes). The horizontal gradient is best examined by looking at the gyres, since in this form of heat circulation, they exert the most influence.

Gyres

Subtropical circulation in the Atlantic is dominated by the Atlantic gyre. This is a large, asymmetrical, clockwise-rotating current system. This system is overlain by a large, high-pressure atmospheric system. This high-pressure atmospheric system sets up a wind-stress field that generates outward-flowing surface currents. In addition to wind-stress-generated rotational momentum (the winds are being deflected clockwise by the Coriolis force), these currents become deflected themselves by Ekman transport (the 45° deflection of a wind-generated surface current to the right of wind direction in the Northern Hemisphere by the

Figure 1 Major currents that drive oceanic circulation

Source: Author.

Coriolis force). The current shear generated by wind stress, frictional forces, and Ekman transport enables the system to acquire relative vorticity, an expression of the tendency of a system to rotate. This is different from the absolute vorticity, which takes into account the vorticity relative to a fixed point and hence includes planetary vorticity—vorticity due to the fact that the Earth rotates. In addition, there is potential vorticity, which factors in the thickness of the rotating body of water and causes the system to shallow (and widen) as it approaches the equator and become narrow and deep as it swings back toward the pole. This is the main way in which topography affects large rotating systems such as the oceanic gyres (seafloor depth controls how deep and hence narrow the current can become). Like all forms of momentum, vorticity is conserved, and its conservation is the mechanism maintaining the gyre.

Boundary Currents

The conservation of vorticity is crucial to understanding the superficial asymmetry of the boundary currents and how they persist within the gyre.

The eastern boundary current (the Florida current) typically has a velocity of ~2 m/s and is usually ~100 km (kilometers) wide. This can be contrasted with the Canary current (the western boundary current), which has an average velocity of .25 m/s and is 1,000-plus km wide. This difference in speed and dimension of the currents reflects difference in the relative vorticity with latitude. As the current moves northward on the western boundary, it gains more negative relative vorticity. In other words, it gains more tendency to rotate clockwise. This is because the Coriolis force increases with latitude, which increases the deflection to the right for northward-moving objects. In the eastern boundary current, the decreasing latitude leads to a loss of negative relative vorticity (or a gain in positive), which acts to slow down rotation. To have an equal volume of water moving northward and southward, the faster western boundary current has to narrow, while the slower eastern boundary current has to widen. Alone, this doesn't ultimately conserve relative vorticity, since wind stress acts throughout the system and is constantly supplying negative relative vorticity. The net result would appear

Figure 2 A Northern Hemisphere high-pressure gyre

Source: Author.

to be a constant speeding up of the gyre's rotation. To balance these forces, friction with coastal boundaries and eddy viscosity (internal friction between moving water parcels) in both horizontal and vertical directions increase substantially as the western boundary current speeds up and acts to slow down rotation. As the western boundary current deepens while it moves northward and the eastern boundary current shallows while it moves southward, potential and absolute vorticity are also conserved, and the gyre is maintained in the form it appears.

Pressure Gradients and Geostrophic Currents

The result in the vertical dimension is that water effectively "piles up" in the center of the gyre creating a horizontal pressure gradient and a

pressure gradient force, deepening the thermocline, and creating downwelling (Figure 2). This results in undercurrents underneath the center of the gyre that flow along the thermocline outward.

The forces that maintain the gyre circulation in the Atlantic are similar in the Pacific; however, in the tropical Pacific, there is tighter coupling between atmospheric and oceanic circulation systems relative to the Atlantic. This coupling is most evident in the system of equatorial currents (Figure 3). These currents are geostrophic in that they represent a balance of horizontal pressure gradient forces and the Coriolis force. Since the subtropics have low average wind velocities, there is no significant Ekman transport there, and the southeast (SE) trade winds actually transport water masses across the equator. The eastward blowing northeast (NE) and SE trade winds also

Figure 3 Equatorial current system

Source: Author.

set up a horizontal pressure gradient in the west as surface currents are deflected 45° to the right and left, respectively, of the NE and SE trade winds and pile up water blocked by landmasses. Below the wind-driven (Ekman) layer, this pressure gradient drives a fast moving equatorial undercurrent within the thermocline. In the doldrums (where the winds slacken), the pressure gradient allows the surface water to flow eastward as the equatorial countercurrent. Since the countercurrent is flowing east, even though it is close to the equator, Coriolis forces are strong enough to deflect enough flow southward that a convergence zone forms between the countercurrent and the south equatorial current. This gives rise to another pileup and a northward downsloping horizontal pressure gradient. This in turn produces another geostrophic current eastward.

Equatorial Current Systems

As shown above, equatorial divergence is created by the SE trade winds crossing the equator. As the wind-stressed currents approach the equator from the south, they are driven away from it (left)

by the Coriolis force (significant at $.5^\circ$). The divergence itself is a function of Ekman transport (the 90° deflection of net transport in the wind-driven layer by wind stress to the right of wind direction in the Northern Hemisphere, to the left of wind direction in the Southern Hemisphere, and in the direction of the wind at the equator). North of the equator, the faster-moving SE trade-wind-driven water masses are deflected northward (right) into the slow-moving mass of water in the doldrums, creating a convergence.

Since it is flowing east, the fast-moving equatorial undercurrent is constrained by the Coriolis force. Although it may oscillate about the equator, if it strays northward, it becomes deflected to the right and returns to the equator. If it strays southward, it is deflected left and also returns to the equator. The wavelengths of these oscillations may nonetheless stretch for thousands of kilometers.

These oscillations illustrate other types of currents important for oceanic circulation. Oscillations in response to an imbalance between the horizontal pressure gradient force and the Coriolis force are referred to as Kelvin and Rossby waves. Both are extremely large disturbance

Figure 4 El Niño–induced Kelvin wave modification of the thermocline in the equatorial Pacific

Source: Author.

correction waveforms, and both can quickly propagate along the equator (Figure 4). For example, during an El Niño year, the thermocline in the east Pacific normally made shallower by steady easterlies is deepened in a pulse or series of pulses as a Kelvin wave propagates eastward along the equator through the thermocline. This propagation does not completely suppress upwelling, however; it merely confines the upwelling to a shallower, warmer zone in which there are far less nutrients from the ocean bottom. Upwelling in the tropical Pacific is mainly a function (both annually and seasonally) of the equatorial undercurrent. In addition, in the eastern basins, mid-ocean upwelling occurs as a result of the relative thinning of the thermocline there as a function of the deepening in the west.

In the tropical Atlantic, the equatorial current system is broadly similar to the Pacific except in the case of responses to changes in the wind field. In this regard, the surface waters of the tropical Atlantic respond more quickly than can be explained by the pressure gradient force derived from water “piling up” in the west. The regions of the ocean in the center and east appear tightly coupled to the west by virtue of the existence of a closer western boundary than in the Pacific. The extreme wavelength of these responses means that they are affected by the Coriolis force and are hence known as Kelvin waves. Thus, in the tropical Atlantic, a change in the west can be communicated east at ~ 200 m/s by a Kelvin wave confined within a certain distance of the equator by Coriolis forces. In the tropical Pacific, the

Figure 5 Monsoonal circulation of the Indian Ocean

Source: Author.

same process can occur, but the opposite sides of the basin are less tightly coupled than they are in the Atlantic. For example, when the Intertropical Convergence Zone moves northward in the western Atlantic, the abrupt change in wind stress causes a double Kelvin wave in the thermocline, a bulge down in front of a bulge up. This baroclinic disturbance is propagated more slowly east along the equatorial waveguide than a surface (barotropic) Kelvin wave.

The Monsoonal Cycle

These equatorial disturbance and adjustment cycles also occur quickly in the equatorial Indian Ocean, although circulation there is more dominated by the monsoonal cycle (Figure 5). The monsoons are seasonal reversals in the prevailing winds as they respond to the weakening from winter to summer of the high-pressure system

over the subcontinent. During the winter, the NE monsoon blows across the Indian Ocean in a manner similar to the NE trade winds. By summer, however, the pattern has reversed, and the stronger of the two, the SW monsoon, dominates, bringing humid air and rain to India. The current system responds to this shift and is most similar to other basins during the NE monsoon. At this time of the year, the typical equatorial current system is present, including the countercurrent. During the SW monsoon, however, the flow of the north equatorial current reverses, merges with a reduced equatorial countercurrent and forms the SW monsoon current.

Monsoonal Current Reversals

Most spectacularly, during the intermonsoon period (moving from NE to SW), the reversal of the north equatorial current and formation of the

SW monsoon current transforms the East African current into a major western boundary current, the Somali current. In accordance with the gyre dynamics described above, this means that the Somali current must be faster (3.7 m/s) and narrower than the eastern boundary current off Sumatra. As the Somali current crosses the equator in its northward travel, upwelling off the Somali and Arabian coast ensues. In addition, the East Arabian Current (EAC) diverges from the Somali current during this period and throughout the SW monsoon to circulate along the coastal boundary of the Arabian Sea. During the next intermonsoon period (SW-NE), the EAC dissipates as the East Indian winter jet forms and flows in the opposite direction along the west coast of India.

Another important current formed during the intermonsoon period (NE-SW and SW-NE) is the eastward-flowing equatorial jet. This jet develops as a result of westerlies-driven surface currents but is insufficient to generate a significant equatorial undercurrent year-round. Unlike the stable tropical Atlantic, the seasonal shifting winds appear unable to sustain a strong pressure gradient force outside the first few months of the year. During this period, the westward-flowing northern equatorial current is strongest, producing brief but strong periods of upwelling. Also, unlike the Atlantic, there is no open ocean divergence in response to trade winds blowing over the equator, since these wind conditions do not exist during either monsoon or intermonsoon periods.

Currents, Eddies, and Water Mass Formation

Finally, there is one way in which the Indian Ocean is similar to the Atlantic, and this is in the presence of a nonseasonal, persistent strong western boundary current—the Agulhas. This current is second only to the Gulf Stream in volume transported and moves at a top speed of 2.5 m/s. The energy transported by the Agulhas is so intense that it pinches off eddies (rings of Agulhas water encircling Indian Ocean water) from the western part of the loop in a process called Agulhas retroflexion. These eddies are transported around the southern tip of Africa into the Benguela current and up the southern Atlantic, where (like eddies

pinched from Gulf Stream) they can last many years. Such eddies illustrate how oceanic circulation, while structured by large-scale, planetary forces, can nonetheless form distinctive water masses. Oceanic circulation thus reflects the interaction of atmospheric turbulence, large-scale convection cells, ocean bottom and coastal topography, and differential heating of Earth's surface and plays the dominant role in redistributing the sun's energy throughout the Earth system.

OCEANS

If geography is the science of space, then few spaces are more important to humanity than the world-ocean. The *world-ocean*—the term preferred by geographers for the “seven seas,” which, in fact, constitute one unified geophysical system—covers 71% of Earth's surface and contains 97% of the planet's water. More than 20% of the world's petroleum is derived from offshore sources, and 95% of world trade by weight, or two thirds by value, is carried by ship. Eighty percent of the world's fish catch comes from the

ocean, supporting the livelihoods of 140 million people. Economists have calculated that the world-ocean provides services to humanity valued at \$21 trillion per year, as opposed to only \$12 trillion per year provided by land. This entry reviews some of the ways in which geographers have approached the world-ocean, a space that is crucial to humanity but is all too often taken for granted as insulated from the influences of society.

A Missed Opportunity

Notwithstanding the important role of the ocean in the world's geography, the world-ocean historically has attracted little attention from human geographers. The history of geography is littered with prominent geographers making strident, but usually unheeded, calls for their colleagues to turn their attention seaward. Almost 2,000 years ago, the Greek geographer Strabo wrote, "We are in a certain sense amphibious, not exclusively connected with the land, but with the sea as well" (cited in Semple, 1931, p. 59). Early in the 20th century, the American geographer Ellen Churchill Semple (1911) admonished her terracentric colleagues when she proclaimed,

Our school textbooks in geography present a deplorable hiatus, because they fail to make a definitive study of the oceans over which man explores and colonizes and trades, as well as the land on which he plants and builds and sleeps. (p. 294)

Forty years later, the geographer Richard Hartshorne (1953) echoed Semple's criticism when he declared that the "fundamental error in popular geographic thought" (p. 386) was the tendency to view the ocean as simply a barrier rather than as a space of human society.

Despite these warnings, human geographers have typically ignored the ocean, probably for three reasons. First, much of modern geography has its origins in efforts by individual states to catalog and manage their resources. Even in social sciences that are less directly tied to the land (e.g., sociology, economics, political science), the state is often taken as the basic unit of society, and global processes are reduced to the category of

international relations (relations among state units). As a space that lies primarily external to the territory or sovereign authority of any individual state, the ocean has, to a large extent, literally been beyond the map of most social scientists.

A second reason why many geographers have long ignored the ocean is the tendency, in both the human and nature-society traditions, to focus on activities that happen in specific places. Geographers historically have understood key social activities, such as production, reproduction, and consumption, as well as the cultural forms that support these activities, as occurring at discrete points on Earth's surface. As the nature of these points is transformed, "places" are constructed, and the territories that encompass these places develop into societies and, ultimately, states. Although the ocean consists of specific points (e.g., fishing grounds, offshore oil platforms), when looked at from a land-based perspective, the ocean is generally seen as a surface across which people and resources (e.g., fish) move, and thus, it becomes excluded from narratives of social development.

A third reason why few geographers have studied the world-ocean is because it is often written off as a space of nature. Although human geographers have a long history of studying nature, this topic typically has either been in the context of understanding how certain natural characteristics shape the people who share the same territory as that nature (i.e., the early-20th-century environmental determinist tradition) or how a specific society transforms its local nature (i.e., the mid-20th-century cultural ecology tradition). However, because the ocean was not the space of any one society, it received little attention from environmental determinists (except, in some instances, in the context of interpreting the role of coastal waters in the development of littoral societies). Conversely, because until recently it was assumed that humans could have little impact on the nature of the ocean, the ocean was similarly of little interest to cultural ecologists. Finally, while physical geographers might have been expected to study the ocean as an integrated geophysical system, this line of research has typically been the domain of physical oceanography, leaving little room for physical geographers to conduct ocean research.

A diver helps fishermen catch tuna fish at a bluefin tuna farm around the mid-Adriatic Croatian town of Zadar, February 2007, before transporting them to Japan. The European Union and Japan agreed to slash their tuna quotas by more than 20% in an effort to prevent the immensely popular fish being hunted to extinction.

Contemporary Issues in Ocean Geography

In recent decades, the world-ocean has begun to attract more attention from geographers. In part, this is because human uses of and interactions with the ocean have been changing and intensifying. However, it is also because geographers have been adjusting their own perspectives and, in the process, opening their eyes to a geography that has always been there.

Environmental and Economic Geography

In the 17th century, when Hugo Grotius was penning the modern doctrine of freedom of the seas in his book *Mare Liberum*, he declared that the ocean beyond the coastal zone should be immune to possession by states because the ocean's resources were inexhaustible, and its environment

was invulnerable to damage from human activities. By the middle of the 20th century, this perspective on the marine environment was beginning to change. Humans had developed an unprecedented capacity to transform the ocean's nature, and technologies had advanced to the point that humans were more able to recognize the transformations in which they had long been engaged.

In recent decades, as economic competition has increased among the world's states (and as competition also has increased within states whose economies are being integrated into the world economy through the processes of neoliberalization), users of the ocean have turned to technological innovations that then have further intensified economic competition. Amid these cycles of economic and technological intensification, the marine environment has increasingly become endangered. For

Oil and gas drilling platform and provider ship in the Pacific Ocean. More than 20% of the world's petroleum is derived from offshore sources.

Source: iStockphoto.

instance, competitive pressures have led fishers to adopt new technologies. These new technologies have not only enabled higher catch rates but also have led to a situation wherein fishers have *had* to catch more fish in order to pay for their expensive equipment. In 2000, the United Nations' Food and Agricultural Organization (FAO) estimated that approximately 50% of the world's fish species were being harvested at their maximum sustainable yield, 25% were being overfished, and 25% could be fished at higher rates. The FAO also noted that the percentage of fish species being overfished had increased significantly since the early 1970s. Furthermore, declining populations of some species have been leading fishers on a race, quite literally, to the bottom, as they redirect their efforts to the ocean's depths, where they are harvesting cold-water species that previously had evaded their attention. These fish, which often are culinary delicacies, typically grow and reproduce at very slow

rates and hence are extremely vulnerable to population collapse and even extinction.

Other ocean-using industries have seen similar increases in recent decades, with equally dangerous environmental consequences. The volume of ship-borne trade has increased from 996 million tons in 1959 to 6,760 million tons in 2005, and this can have an impact on the environment, both from wrecks (most notably of oil tankers) and from normal operations (e.g., discharge of bilge water). The National Ocean Industries Association, a U.S. industry group, estimates that 44 million gallons of petroleum are released into the ocean annually by tanker ships, and additional quantities of petroleum and other pollutants are released by ships transporting goods other than petroleum. Discharged ballast water can endanger the marine environment by introducing invasive species that have been transported from a distant area of the world-ocean.

Additionally, effluents from industrialization, urbanization, and chemical agriculture on land increasingly find their way to the sea, joining waste products that are being dumped there intentionally. Furthermore, as oceanographers have gained a better understanding of ocean currents and marine geophysics, they have realized the magnitude of the connections among the world's oceans: What seems like a local environmental problem could have global implications.

In addition, as climatologists have learned more about periodic climactic events (e.g., the El Niño Southern Oscillation, the North Atlantic Oscillation) and global climate change, they have gained an appreciation of the ocean's role as both an indicator and a regulator of trends in the world's climate. An increase in the atmospheric temperature, for instance, would raise the temperature of the ocean. This, in turn, could lead to disastrous impacts for fish stocks, human populations (because of increased storm activity), and ocean circulation systems. Alterations in the ocean circulation system, in turn, could further affect local climates, creating a vicious cycle of climate change in which the ocean would play a leading role.

Increased scientific understanding of (and concern for) the marine environment has been supplemented by a growth in public awareness. The adventures of celebrity explorers like Jacques Cousteau, the writings of environmental travel writers like Carl Safina, the interventions of policy advocates like Sylvia Earle, and the warnings of environmental muckrakers like Rachel Carson have all alerted the public to the world's endangered marine environment. These authors have been assisted by images of the globe from outer space, which illustrate the significance of water on the "blue planet." They have also been assisted by the ocean's image as a pristine space of nature, a mysterious space of wonder into which one should be able to escape from the institutions and influences of human society. Environmentalists, in turn, have reproduced these ideals of a pristine, exotic ocean by focusing on iconic marine fauna and flora, such as whales, manatees, and coral reefs, in their efforts to raise global environmental consciousness.

Increased awareness of the ocean by environmental geographers is not only due to our increased ability to transform the ocean and

popular awareness of these changes but also due to changing perspectives within the discipline itself. To some extent, this changing attitude has come from political ecologists who are increasingly attentive to the ways in which the Western model of constructing nature through taming it, controlling it, binding it into private property, and "improving" it (i.e., the agricultural model) is just one way among many in which societies productively interact with nature. It has also emanated from increasingly sophisticated theorizing about nature, wherein nature is seen not as something with which societies *interact* but rather as something that societies *construct*, through combinations of economic regimes, state strategies, and applications of knowledge systems.

Political Geography

Individuals and institutions attempting to regulate the ocean as a space of nature and economic activities have had to weave between two opposing imperatives in ocean governance. On the one hand, some areas of the ocean, particularly near the coasts, are much like land. Fishing grounds and offshore oil fields are designated as places to be controlled and developed so that their resources can be mobilized for the benefit of states and societies. Presumably, the best way to foster the development of these ocean territories would be to expand the boundaries of the territorial state out into the adjacent sea.

On the other hand, the bulk of the ocean's value is derived from it being a space of mobility. Economically, more value is derived from transport across the ocean's surface than from fishing and mining activities combined, and if state territory were extended into the sea, it would interfere with the interests of shipping and navies, which depend on the sea being a relatively open space, with few boundaries, rules, or policing authorities. Indeed, shippers and navies have long been wary of efforts to govern and patrol the ocean, for fear that these efforts might encroach on the "freedom of the seas" that they enjoy. Furthermore, fish and pollutants are mobile as well. If one country chose not to fish a certain species in order to conserve it, that fish would likely move into another country's territory. Likewise, a country has little incentive to curb a pollution release

if it knows that the pollutant will likely float into another country's space.

In short, although enclosure of the ocean may be a good strategy for fostering coastal development, the ocean's physical properties and its dominant economic uses make it an unsuitable policy for extension across the world-ocean. Instead, international policymakers, over time, have agreed on a compromise, codified in the United Nations Convention on the Law of the Sea. Under the 1982 convention (which went into effect in 1994), coastal waters out to 12 nm (nautical miles) are considered territorial waters. Coastal states have most of the same rights there that they have in their land space, except that they must allow passage by ships of other states that are deemed "innocent." The rest of the ocean is the high seas, where no country controls the water but where the ship is considered an extension of the country under whose flag it flies. There are, however, two key exceptions to this delineation of ocean space. The portion of the high seas between the 12-nm limit of territorial waters out to 200 nm is the coastal state's exclusive economic zone (EEZ). Although high seas' navigational freedoms prevail in an EEZ, the coastal state retains exclusive rights to the living and nonliving resources that are found there or on the underlying seabed. Conversely, international straits that are fewer than 24 nm in width (and that thus lie entirely within territorial waters) are governed by a right to free transit that is stronger than the right to innocent passage that applies in other territorial waters.

As is the case with environmental and economic geographies of the ocean, the interest of political geographers in the ocean has been aided not only by the increased intensity of ocean governance and conflict but also by changing perspectives within the subdiscipline of political geography. Political geographers and political scientists have traditionally begun their analysis by studying individual states and the relations between them. From this perspective, the ocean, as a space outside the territory of any state, emerges at best as a space used by society: an arena in which the forces of land-based states meet as each attempts to control crucial areas of the sea (e.g., a choke point on a shipping lane) or to use the ocean as a platform from which power can be projected onto land.

In recent decades, however, two perspectives—world-systems theory and poststructuralist thought—have become increasingly popular in political geographic studies, and these have led to a reevaluation of the ocean as an integral space of society. For world-systems theorists, the world, rather than consisting of 190-odd state-society units, consists of one integrated (albeit spatially differentiated) social system. This is significant because if one thinks of the world as consisting of one society, with many constituent varieties of spaces, then the ocean shifts from being conceived of as an external space *between* the world's societies to being conceived of as one of the many spaces *of* society.

A second theoretical movement that has spurred a growing interest in the political geography of the ocean has been poststructuralist international relations theory and the aligned school of critical geopolitics. These scholars criticize the model of the world as one in which states with unambiguously bounded insides interact with each other on a preexisting (and presocial) spatial platform. Instead, for these scholars, the discursive bounding of states and the construction of the world as a universe of mutually exclusive territorial states is itself seen as an act of politics—one that is continually being performed. Since the ocean is a key borderland wherein states define their extent (and hence themselves), the ocean emerges as an important arena for state reterritorialization and not merely a surface on which ontologically preexisting states compete.

Cultural Geography

While the increased attention to the ocean in environmental, economic, and political geography is due to a combination of increased uses of the ocean and changed perspectives within the discipline of geography, the increased attention in cultural geography is almost entirely due to changes in the discipline. Although the ocean has long been a site of interaction between cultural groups and a realm within which coastal dwellers have subsisted on local natural resources, historically few geographers have devoted their attention to the cultures of fishing communities and even fewer have studied the cultures of societies engaged in uses of the deep sea (e.g., whalers, naval personnel, merchant

mariners, oceanographic and fisheries researchers, or long-distance fishers).

In recent decades, however, much of cultural studies—including cultural geography—has abandoned attempts at understanding distinct and bounded societies (which typically occur in place and, not incidentally, on land). Instead, students of culture from a range of disciplines, including anthropology, literary studies, and history, as well as geography, are increasingly turning their attentions toward the interactions that occur and the hybrid cultures that are formed in the spaces where cultures meet. As part of this trend, a range of classic works from outside the discipline have focused on the sea (or the ship) as a point of interaction and hence culture formation. Among these works are the social historian Fernand Braudel's *The Mediterranean and the Mediterranean World in the Age of Philip II*, wherein the sea is identified as a fundamental space in a Mediterranean civilization defined by commercial interaction; the sociologist Paul Gilroy's *The Black Atlantic*, wherein the African diaspora is identified as having distinct qualities because it is associated with an integrative ocean rather than a stabilizing land; and the labor historian Marcus Rediker's *The Devil and the Deep Blue Sea*, wherein the seafaring ship is seen as a crucible for the emergent labor regimes and solidarities of industrial capitalism. This focus on the sea as an arena for culture formation, in turn, has been given further weight by theorists, including Michel Foucault, Gilles Deleuze, and Felix Guattari, who stress the metaphorical significance of the ship or the ocean for understanding spaces of alterity ("heterotopia" in the case of Foucault and "smooth space" in the case of Deleuze and Guattari).

Thus, the inattention to the ocean that characterized so much of the history of geography has been turned on its head. The world-ocean was long ignored by geographers as a zone of resources or a surface for movement that was fundamentally external to society. Now, however, in a dramatic shift, the world-ocean is emerging as a space through which geographers make sense of the land spaces in which they dwell.

OFFSHORE FINANCE

Offshore finance refers to financial transactions that take place in jurisdictions that are either literally or jurisdictionally separated from the major economies of the onshore world, such as the United States, Britain, Japan, or Germany. Offshore financial services are transacted from offshore financial centers (OFCs) found in dispersed locations throughout the planet. Although no firm consensus exists in the academic or business worlds as to the number of OFCs, most offshore jurisdictions are small independent or semi-independent island nations with spatial clusters found in the Caribbean basin and in Western Europe and in isolated locations in Asia and the Pacific region. This topic is of importance to geographers because the offshore world is often at the spatial margins of economic activity where many of the problems of the modern global economy are found: extremely unequal tax practices, money laundering, and terrorist financing. This entry addresses reasons for the creation of an offshore financial sector, the current distribution of OFCs, and reaction to the growth in offshore finance by the onshore world.

Development of Offshore Finance

Offshore financial transactions and OFCs became more relevant and visible as the global circuitry of capital grew in size and intensity in the second half of the 20th century. The global financial system evolved and grew in sophistication and complexity because of several developments, including the dissolution in the 1960s of the post-World War II Bretton Woods system of fixed exchange rates pegged to the U.S. dollar; the subsequent

creation of the Eurodollar market (“Eurodollars” are U.S. currency held in banks located outside the United States, and “Eurocurrency” is any major currency held in banks outside the country of issuance); the growth in Middle East petrodollar recycling in the 1970s; and technological improvements in the latter part of the 20th century in electronic telecommunications and data exchange. Current estimates show that as much as half of the world’s stock of money either resides in or flows through these places.

Spatial Distribution of OFCs

No consensus exists as to the number of OFCs transacting financial services in the global economy. Supranational regulatory and supervisory bodies such as the Organisation for Economic Co-operation and Development (OECD), the European Union (EU), the Financial Action Task Force (FATF), or the Basel Committee Offshore Group of Banking Supervisor (OGBS) vary in the number of OFCs defined and listed. In addition, trade bodies such as the Lowtax Network identify more. Table 1 shows a current list of low-tax jurisdictions as defined by Lowtax.net, with those members of the OGBS so identified. These places—many of which are small island economies—number at least 40 and are scattered throughout the planet. The factor they have in common is the use of accommodating (often described by critics as minimal) legislative, regulatory, and supervisory infrastructures to attract capital by marketing tax minimization, secrecy, and confidentiality of service and product.

Offshore-Onshore Tensions

The first serious reaction from the onshore world toward regulating the financial activities of the offshore world came with the 1998 initiative by the OECD addressing harmful tax competition as an emerging global issue. The OECD’s concern over existing inequities led to specific guidelines published in the form of a so-called blacklist of most jurisdictions labeled as tax havens, and OFCs were then charged with establishing guidelines for increased transparency when reporting financial transactions.

The EU followed the lead of the OECD by establishing initial tax-harmonization policies

for its member states in 2000, but progress was slow as the ever-expanding EU had other pressing issues to address. A savings tax agreement was reached by 12 member states of the EU in 2003, and this directive involved the commitment by states to introduce an automatic exchange of information concerning interest income from the savings of residents of other member states. The goal of creating a level playing field for taxation has been furthered by this agreement, and even though the policy is directed initially toward the internal market, the EU also has tax policy issues directed externally. In an external savings directive, the EU specifically targeted the nonmember jurisdictions of Switzerland, the United States, and other important financial centers, including all relevant dependent or associated territories.

In 1989, in response to concern over money laundering, the FATF was created by the G-7 economies. Money laundering was defined as the processing of illegal profits from a variety of activities, including illegal arms sales, smuggling, drug trafficking, prostitution, and other activities of organized crime, as well as white-collar crimes such as embezzlement, insider trading, bribery, and computer fraud schemes.

According to FATF, criminals seek to launder illegal profits by disguising the sources or moving

the funds to a place where they are less likely to attract attention. As confidentiality is one of the major selling points of OFCs, FATF and the other onshore regulatory and supervisory bodies have tried to establish policy initiatives to promote transparency in financial transactions and to establish anti-money-laundering systems for OFCs in compliance with the FATF guidelines. The most fundamental element for offshore anti-money-laundering policies is the “know-your-customer” requirement that many offshore financial institutions and centers currently use. Know-your-customer policies require official proof of identification using passport and other official documents and include monitoring and reporting of any suspicious transactional activity.

For OFCs, the establishment and preservation of a superior reputation as a well-regulated and supervised jurisdiction is considered to be one of the most important marketing strategies for competitive advantage, and most OFCs work with FATF and other onshore organizations to remain in good standing and protect the reputation of the center.

OIL SPILLS

Oil spills are the release of petroleum into the sea or inland areas and are a major threat mainly to coastal environments. In the past century, there was a notable increase in world population, in general, and in the coastal population in particular. Hence, coastal areas' vulnerability to oil spills has increased, often to the level of potential natural and human catastrophes.

Oil is mainly exported by maritime traffic from oil-exporting areas, such as the Persian Gulf, Libya and Algeria, Nigeria, and Sudan in Africa to the major oil-importing countries, namely, the United States, Western Europe, Japan, India, and China. In the 1990s, some 3.4 million tons of oil, or 0.01% of the world's total annual oil production—about 3.6 billion tons/year, went into the sea. Approximately, 47% of this volume was from oil spills from ships, the rest from industrial plants, sea oil drillings, and natural sources. Generally, major oil spills are caused by shipping accidents at sea, fires on tankers, or ship accidents on coastal barriers. The total risk, or the expected number of injuries and lives lost and amount of property damaged, is a function of the magnitude of the hazard—oil spill in this case; the number of potential economic

and environmental assets to be affected, such as beaches, ports, nature reserves, and so on; and the vulnerability of the affected area.

Oil Characteristics

Crude oil is a naturally occurring complex of liquid hydrocarbon, which after distillation yields a range of combustible fuels. Four different types can be distinguished from the viewpoint of oil spill threat to the environment:

1. Light fuels, such as gasoline, kerosene, or fuel oil
2. Medium to heavy oil, such as ship fuels and light lubricants
3. Oil rich in paraffin, such as water-oil emulsion and heavy-oil lubricants
4. Residual oil, such as asphalt and heavy-oil residuals

The following are the oil characteristics that need to be taken into account in an oil spill: (a) *density*, which determines the dispersion and floating of the oil (heavy-oil density is above 0.9, light-oil density is below 0.865, and fuel-oil density is 0.84); (b) *viscosity*, or resistance to flow; (c) *boiling point*, which determines the rate of evaporation; (d) *pour point*, namely, the temperature at which oil is transformed into a gel, depending on the oil composition; (e) *flash point*, or the lowest oil temperature to maintain a layer of vapor, an important factor to reduce fire risk; and (f) *dilution*—light fuels are easier to dilute in seawater but are poisonous to the living environment. Oil is an organic compound and is transformed in seawater by complex physical and chemical processes until it “disappears” completely. Light and medium oils dilute and evaporate in seawater after one day, but the heavy fractions with high viscosity may remain and are hard to dilute with dispersants. In such cases, removal of oil by mechanical means is best advised.

In a tropical climate, about 80% of the oil evaporates on the first day of the spill. Light fuels become diluted in seawater but are dangerous to the biota, and on reaching the shore, they are absorbed by coastal sand.

Aerial view of the Deepwater Horizon oil slick off of the Mississippi Delta on May 24, 2010. Not technically an oil spill but a pipeline gushing oil from a mile below the surface, it created the largest oil disaster in U.S. history, with devastating consequences for the local ecologies and economies of the Gulf Coast.

Oil Spills in the Ocean

What happens when there is an oil spill in the ocean? Despite the spillage of tens of millions of tons of oil into the oceans over many years, evidence does not exist of irreversible damage to seawater or even to the coastal environment, according to a report by the International Tanker Owners Pollution Federation. However, fragile coastal environments that become heavily polluted may suffer for many years until recovery is complete. In the initial period, the damage to densely populated coastal areas or seaside resorts may amount to great economic cost.

After the spill, oil not only undergoes a series of physical and chemical processes but is also carried by the product of two vectors: the waves and surface sea currents (Figure 1).

The “weathering” of the oil, or its dilution in seawater, is a function of several factors: the magnitude of oil spill, oil composition, oil dispersion as one body or several small patches, oil viscosity and density, air and water temperature, wind and wave velocity, and more. The oil may lie several tens of centimeters thick near the source, but after dispersion, its thickness is only a fraction of millimeter; eventually, it turns into a sheen blanket only a few micrometers in depth.

Figure 1 Oil spill carried in seawater by a vectorial result of wind and sea current forces

and floating obstruction devices to prevent oil flowing to the coastal area. Pumping is also used to recover part of the oil. Chemical techniques, such as dispersants or chemical devices, cause the oil to sink. Biological techniques, by means of microorganisms and chemical fertilizers, increase the bacterial activity of oil disintegration. Burning the oil is not recommended in many countries because of the atmospheric pollution, but it may be applied in critical situations. In some cases, the “don’t interfere” method may be adopted; only monitoring of the flow and direction of the oil patches is carried out.

One ton of oil may cover 1 km² (square kilometer) of seawater after just a few hours, and then it divides into long strips.

In spring 2010, the largest marine oil disaster occurred in U.S. history. The Deepwater Horizon oil rig, under contract for British Petroleum, exploded, killing 11 workers. A mile beneath the surface, a pipeline gushed crude petroleum, which rose to the surface to form an enormous oil slick. (Thus, technically, this was not an oil spill, such as happens when oil tankers leak petroleum.) The source of the oil proved to be very difficult to control. The resulting pool of petroleum gradually moved toward the coastline of Louisiana and neighboring states, threatening coastal ecosystems and local fishing and shrimping industries.

Cleaning Oil Spills

Several methods are used to clean oil spills. Mechanical techniques include containment

Environmental Sensitivity to Oil Spills

The overall sensitivity of an environmental system to oil spills has three major aspects:

1. **Vulnerability** is the ease with which oil may reach and persist in a certain ecosystem. Vulnerable ecosystems are those where oil may penetrate easily and remain for lengthy periods, where wave energy and currents that could disintegrate the oil are low, and where mechanical or manual cleaning may be difficult owing to low accessibility. In general, vulnerability may be defined as the exposure of economic and environmental assets to the oil spill.
2. **Sensitivity** refers to the particular components of the biota. Sensitive species are those that may be affected directly immediately after the spill, as biological systems become clogged with oil; species whose way of life will bring them

into close contact with the oil spill; and species with a low reproduction rate.

3. *Resilience* is the way biological populations can resume their natural behavior. Highly resilient species are those with a high reproduction rate, short life expectancy, high physiological resilience, and wide geographic dispersion.

Socioeconomic and Political Aspects

Major oil spills, such as the *Prestige* tanker spill in November 2002 off the Atlantic coast of France and Spain, generally involve a high economic cost—around US\$1 billion. In 2009, the European Parliament approved a directive to all members to impose penal sanctions against heavy and continuous pollution. Some polluters are not deterred by fines, and to save money, they continue polluting.

Here are some examples of political and economic conflicts. Between 1964 and 1990, oil exploration and drillings in the Ecuadorian Amazon region polluted an area of 4,000 km². The U.S. companies involved denied responsibility and blamed the national Petroecuador Company. Local ethnic peoples and much of the environment were affected. In 1999, a Dutch oil ship spilled about 5,300 tons of oil into the Rio de la Plata, about 100 km south of Buenos Aires. The spill was 30 km offshore and affected the beaches. The local council of Magdalena was given US\$9.5 million to develop tourist facilities. The Sea Division of the United Nations Environment Programme is responsible for international agreements between coastal nations to prevent oil spills and to coordinate management in case of a spill.

OKABE, ATSUYUKI (1945–)

Atsuyuki Okabe received his PhD from the University of Pennsylvania in 1975 and a doctor of engineering degree from the University of Tokyo in 1977. He was the director of the university's Center for Spatial Information Science (CSIS) from 1998 to 2005. He is currently a professor at the University of Tokyo and a member of the Science Council of Japan.

Okabe was one of the first to apply Voronoi diagrams to the spatial competition problem (Hotelling problem) and showed that the equilibrium states in a two-dimensional (2D) space were drastically different from those in a 1D space. Since then, he has extensively studied Voronoi diagrams, and his outcomes were developed into a book, *Encyclopedia of Voronoi Diagrams*, which provides a general framework for studying Voronoi diagrams and illustrates hundreds of applications in various fields. It has been cited in more than 1,700 articles.

He also broadened the applications of geographic information systems (GIS) to the humanities and social sciences. One book pioneered the systematic applications of GIS to Islamic studies, which was well received and earned him the World Prize of the Book of the Year of the Islamic Republic of Iran. Another book developed the frontiers of the applications of GIS to the humanities and social sciences.

He developed new spatial analysis, namely, spatial analysis on networks. Traditional spatial analysis assumes that space is given by a plane with Euclidean distance. Okabe proposed a new paradigm, where space is represented by networks embedded in the 2D or 3D space with the shortest-path distance. In addition, he and his colleagues developed a toolbox for spatial analysis on networks called SANET. SANET is now used by researchers in more than 40 countries.

Furthermore, he published a series of articles on city systems. Okabe theoretically analyzed the relationship between the optimal city-size distribution and Zipf's rank-size rule. He developed an integrated theory that combines a macro-empirical law, the rank-size rule, and a micro-empirical law, the Clark's law of urban population distribution. Okabe and colleague Sadahiro demonstrated why Christaller's city system could be observed in the real world using spatial random point processes.

He has contributed tremendously to the development of research in spatial analysis and geographic information science. In short, he is *the* founder of these fields in Japan, both in research activity and in terms of organizing a research organization, namely, CSIS in the University of Tokyo.

OLSSON, GUNNAR (1935–)

Gunnar Olsson served for a decade as professor of geography at the University of Michigan and for 20 years as director of the doctoral program at the Nordic School of Planning (*Nordplan*) in Stockholm, before returning to Uppsala University in the late 1990s. He has become one of the more influential deconstructive voices within poststructuralist geography. Idiosyncratically drawing on reactionary and rebellious ideas from geometry, philosophy, theology, cartography, semiotics, and aesthetics, the political implications of Olsson's work have been a constant source of academic controversy.

Olsson completed his doctoral studies at Uppsala University in 1968. His early work dealt with distance and human interaction and was based on methods emanating from the quantitative tradition in geography. From the 1970s onward, Olsson has been a key figure in the development of post-positivist geography. He soon acquired a reputation as a radical avant-garde writer, laying out his critique of power and modern reason in texts of intimidating difficulty. Notwithstanding this, a considerable share of this work can be said to have emanated from practical experience and an early dissatisfaction with the tight collaboration between (applied) geography and modern planning practices. In Olsson's native Sweden and elsewhere, geography played a vital role by supplying planners with what was conceived as useful scientific knowledge, maps and models. Olsson's interrogation sought to dissect the taken-for-granted ideas keeping the two together. In particular, he targeted the widespread postwar planning principle that specific modes of living and behaving would result from deliberately

designed changes in institutional and spatial structures.

Olsson argued that this whole enterprise was based on false premises. Processes and forms did not necessarily correspond, and it remained impossible to predict the consequences of general schemes and actions. Instead of further advancing the modeling and mapping impulses of geography, Olsson identified an insurmountable gap between academic reflection and the pragmatic implementation of knowledge. Geography's peaceful association with planning and welfare capitalism had to be replaced by a self-reflexive, more radically humanistic geography, shifting its focus to living individuals and a trenchant scrutiny of power. Power could be seen as a game of ontological transformations, turning invisible relations into visible things, mindscapes into stonescapes, and vice versa. This theme led Olsson to the deconstruction of a whole series of frequently taken-for-granted practices and relationships, such as those between thought and action, individual and collective, certainty and ambiguity, language and phenomenon, expression and impression, stability and change, mind and body, and creativity and socialization.

Olsson's radical cartography of power earned considerable resonance internationally and was popularized for a Swedish audience in a collection of essays, *Antipasti* (1990). In the early 21st century, many of his earlier ideas were drawn together as a wholesale critique of cartographical reason in Western society—*Abysmal* (2007). For Olsson, a critique of cartographical reason concerns not simply the way in which mapping is socially employed as a material instrument of power and knowledge. A map is also a document of mistranslation, a story confronting us with absences and silences and hence with the limits of language and representation. Maps can be understood as signs closing the abysses between the five senses of the body and the sixth sense of the cultural taken-for-granted. More important than their ability to reflect reality, maps have an authoritative power to convince: They are exemplars of given- and taken-for-granted modes of thought and action. In this expansive sense, Olsson's critique of cartographical reason gestures beyond mapping and geography and involves no less than an assessment of what he sees as the

currently ruling mode of thought and action. It is concerned with the broader study of people as semiotic animals—a species whose individuals are joined and separated by the use of their signs, including maps—with the inner world of that which structures, authors, and controls, for instance, mapmaking and geography. The self-imposed task of Olsson's "heretic cartography" is to question the authority and power implied in such ostensibly prearranged givens and truths.

ONTOLOGICAL FOUNDATIONS OF GEOGRAPHICAL DATA

How can data users obtain geographical data that is relevant or at least closely related to their interests? One solution is to understand what geographical data really mean. How to describe the meaning of data? Metadata, which consist of information such as keywords and positional accuracy about the data, seem to solve half the problem. Metadata include geographical terms such as *river* and *mountain*, which are used to describe the content of a given geographical data set. These terms, however, are often ambiguous: Two different terms can refer to the same thing

for different people. For instance, *river* and *stream* or *hill* and *mountain* are different terms that can refer to the same feature. How can one resolve such issues, or at least mitigate the conceptual and terminological differences between the terms, so that when one looks for geographical data about rivers, the data on streams could also be considered? Current approaches, which apply exact string matching, generate only geographical data that are described with the same string. To support information retrieval, the meanings of geographical terms associated with given data should be made explicit. Making the meanings of geographic terms explicit makes it possible to carry out matching to see whether the data involved describe the same thing. This entry discusses the ontological foundations for geographical data. By comprehending its ontological foundations, one is able to describe a geographical term more precisely, which assists in retrieving closely related geographical data.

In what follows, some terms are defined to serve as the background context for the readers, including *ontology*, *ontological commitments*, *semantic heterogeneity* and *interoperability*, and *semantic similarity*. Next, the ontological foundations are explored based on the semantic, pragmatic, and spatial aspects of geographic data. On the semantic aspect, the notion of ethnophysiology, which aims to study the semantic meanings of geographical terms in different languages and cultures, is discussed. The study of geopragmatics, which focuses on representing the application contexts of geographical data, is outlined. Last, the notions of bona fide and fiat boundaries of geographic features, and the granularity of geographic space, will be described.

Background Context

The term *ontology* originated in philosophy to refer to the science of what is, that is, the kinds and structures of objects, properties, events, processes, and relations in every area of reality. From a philosophical perspective, ontology describes the constituents of reality, and the relationships among these constituents. Referring to the geographic domain in particular, geographical ontology describes geographic features

(human-made and natural), categories, relations, and processes at different scales or spatial granularities (different levels of detail in representing spatial entities). The term has also been used in the information sciences community. Slightly diverging from its meaning in philosophy, ontology in the information sciences is a logical theory about how information systems operate. This type of ontology is defined as an explicit specification of a conceptualization (with *conceptualization* often referring to the perspective of the software developers who build the systems). In other words, from the information sciences perspective, ontology is a description of the viewpoints of developers, which humans can read and that machines can process. Different ontologies can exist for different information systems. To differentiate the conceptions being used in the two domains, the term *ontology* in philosophy is used in the singular, whereas in information sciences, the term is plural—*ontologies*.

According to philosopher Willard Quine, ontology involves *ontological commitments*, that is, the ontological presuppositions embodied in different scientific theories. For example, the statement that A is a body of water entails that A exists in the real world (not simply as an idea) and contains water. Therefore, given that different groups of people (e.g., scientists, software developers, teachers) have different ontological commitments (they study different things and may give different meanings to the same group of real world observations), incompatibilities in terminology inevitably arise.

In geographic information systems, each entity (represented either by points, lines, polygons, or pixels) can be associated with attribute information of objects, such as the location, height, and colors of rivers and mountains. This attribute information indicates what feature the entity actually demonstrates in the real world. A question arises when the same dataset is described by different attributes. This issue becomes critical in sharing geographic information across different organizations and people with different worldviews. The issues resulting from semantic differences are called *semantic heterogeneities*. One way to mitigate these issues is to use ontologies, which are designed to explicitly describe information

contents and to allow one to see if the information contents to be shared refer to precisely the same thing. A paradigm that is envisioned to integrate semantically heterogeneous information contents is referred as *semantic interoperability*.

For example, is a river more similar to a lake than to the sea? The degree of conceptual closeness between two terms/concepts is called *semantic similarity*. The semantic similarity between two concepts is measured generally based on the comparisons of the characteristics of a concept in respect to the characteristics of another concept. For example, a river could be considered more similar to a lake since both contain fresh water, as opposed to the sea, which contains salt water.

Semantic similarity is not symmetric and is context-dependent. The characteristic of being asymmetric means that the degree of similarity when comparing a first concept to a second concept is not identical to the degree of similarity when comparing the second concept to the first. Two concepts are semantically asymmetric when the degree of similarity between A and B differs from the degree of similarity between B and A. For example, research shows that people tend to think of a hospital as being more similar to a building than a building is similar to a hospital, because the term *building* contains a more heterogeneous group of objects; that is, a hospital is a subset of the larger set of buildings. Semantic similarity is also context-dependent, meaning that the criteria to be considered for a measurement affect the degree of similarity. For example, if the similarities among rivers, lakes, and seas are based on the salinity of water, then a river is more similar to a lake than the sea. But, if the shape of the features is to be taken into consideration, one may think that a lake is more similar to the sea than a river, in that a lake and the sea usually have a dislike shape compared to a river, which is generally formed as a linear feature. Measuring semantic similarity is crucial in information integration and retrieving relevant information. If two information sources are highly similar in a given context, one can integrate them more confidently than if they are dissimilar. Likewise, if information content is highly similar with a query (e.g., by checking the similarity between the terms used in the information content and the query), such information content can be retrieved for the users.

Ontological Foundations

The discussion above deals with terms in English; more complex problems emerge when multilingual terms are involved. In such cases, cultural differences can also play an important role. *Ethnophysiography*, a term originally coined by David Mark and Andrew Turk, attempts to investigate how and why the terms referring to the landscape and its components are used in different languages and cultures. Mark and Turk have studied geographic feature terms from different languages such as Australian, Yindjibarndi, and Najaro.

In addition to differences in language and culture, the application context of geographical data should also be considered as another important ontological element for geographical data. For example, because different cultures have different ways of gathering and making sense of real world observations, a conceptual mismatch may occur when merging geographical data at the border of two very different cultures. A “geopragmatic” view is necessary in resolving such a mismatch. Originating from a pragmatic perspective, geopragmatics emphasizes scientific concepts related to geographical models. Geopragmatics has three core aspects: dimensions, agents, and roles. Dimensions encompass the origins (provenances), uses (deployments), and effects (consequences) of a concept. Agents are referred to as the interactions among humans, machines, and the real-world geographic features themselves. Roles consist of perspectives and versions. Perspectives are method driven (e.g., a remote sensing perspective, or an image analysis perspective), while versions are epistemically driven. More specifically, an observation can have one perspective (e.g., using a particular method such as remote sensing), but because different agents, intentions, repetitions could be involved in the same observation, different versions could be produced.

Two types of boundary can be classified for describing geographic features in the real world, the bona fide boundary and the fiat boundary. For geographic features that have the bona fide sort, their boundary has been delineated with physical demarcations such as coastlines. The border of Singapore belongs to this category, in that it is an island. In contrast, the fiat sort of boundary is intuitively formulated by humans’

mutual agreements for purposes such as land administration or political subdivisions. The state of Colorado has a boundary of this sort, in that its borders do not correspond with physiographic features. In a mathematical sense, a bona fide boundary is transitive (e.g., if x is a boundary point for a line segment y , and y is the border of Singapore, then x is also a boundary point for Singapore itself), disjunctive (e.g., if x is a part of y , and y is the border of Singapore, then x is a part of the border of Singapore also), and symmetric (e.g., if y is the border of Singapore, y is also the border of the ocean that completely surrounds Singapore), while a *fiat* boundary is transitive, disjunctive, and not symmetric because a fiat boundary is considered as an intrinsic part of the feature that the boundary binds; it does not belong to the complement of the feature.

Humans perceive the world at different levels of spatial granularity or scale. Granularity is perspective-dependent, meaning that humans can think of a specific object such as lake from a very fine-grained level to a highly coarse-grained level. At the very fine-grained level, for instance humans can imagine the lake as a very large volume of water in which millions of H_2O molecules interact with each other, and at the coarse-grained level, the lake could be imagined as a dot just like it is viewed from outer space. In the geographic domain, the notion of granularity results in geographic maps being produced in different scales, or the same geographical data set can be created in multiple representations. Granularity is critical in interpreting geographical data. If the data are presented at a fine-grained level, they could reveal detailed relationships among the features involved. If the data are at a coarse-grained level, one is able to visualize the overall patterns among features, for instance, in different clusters. As granularity determines the relationships among geographic features, any formal model attempting to represent the interrelationships of geographic features should concern the granularity of the geographic space in which the features under consideration are located.

ONTOLOGY

Spatial ontologies are formal arrangements of geographic features based on the meaning of their terms and relation to each other. Taken from the field of philosophy concerned with *ontology*, or the study of what is real in the world, the role of

ontology in geography is to formalize knowledge bases (logical structures of geographical knowledge) and to recognize, exchange, and support common geography cultures through the use of the semantics, or meanings, that groups of people assign to geographic features and spatial relations. Within the established scope of the ontology, the features imply definitions and descriptive qualities. Relations among features have a range of meanings or specific values. Although the articulation of an ontology is a largely abstract endeavor, its elements are derived from empirical investigations. Ontologies are intended to refer to the real world.

Geographers turn to the underlying ontology of a study, as it is expressed, to examine the implications of the terms and semantics of the subject. Ontologies are discussed in the geographical literature as foundations of studies and, as such, are subject to analysis to understand the limitations and motivations of those studies within their scope. Although ontology implies the acceptance of a realist philosophy, its abstractions leave the scope of the ontology open to interpretation. Concepts of ontology often appear as the transition between epistemology and methods—a key concept in geographic thought, philosophy, and theory, with implications in specific subfields of geographic practices. Geography methods aim to capture the nature (the ontology) of their subjects, while recognizing that knowledge is affected by social (epistemological) implications.

Ontology in geography has been linked to a broader recognition of diversity, in the hope of making those differences explicit and thereby enriching the knowledge base of geographic activity. This task has been accomplished by turning to the immediate realism of interconnected themes of place, environment, society, and philosophy. Ontology is used in analyses of key concepts of geography, such as networks and globalization; urbanism and agrarianism; history, economics, and culture; and nature and the environment. Social developments such as feminism and postcolonialism have been furthered by discussions of their ontology.

Ontology can be structured by geographical concepts such as scale and generalization. Geographical features are often viewed as embedded in hierarchies of scales and taxonomies of classes. Though the formations of these classes have been studied in relation to psycho-cognitive experiences,

some categorization concepts bias views of the world by “covering up” factors and agents—for example, ideas of globalization. In contrast to hierarchies of geographical extents, flat ontology explores concepts of sites as context to geographic features and relations. These sites have both stable, structuring forces and potentials for new opportunities of expression. Through processes or the activation of relations, the mutable spaces and composition of sites emerge as new potential environments. Thus, ontology can be regarded as transformative. Concurrently, however, a central concern of history and historiography in geography is fundamentally ontological: How do we conceptualize and accept what was real about the past?

Ontology appeared prominently as a core concept in geography as Marxism critiqued Aristotelian ontology; briefly stated, this argument is that no objects are just simply “out there” in the world. Instead, elements, things, structures, and systems exist within the processes, flows, and relations that create, sustain, or undermine them. To define things relationally is different from direct observation that posits features as being self-evident rather than as a product determined by history and politics. The postmodern recognition of the importance of geography led to a new interest in the ontology of geography. Embracing spatiality, temporality, and social being as a part of the material world, ontology and postmodern geography recognize social constructs as shaping and simultaneously being shaped by the empirical world.

Ontology is seen as a framework for the interaction of society and nature beyond the dualisms of man and environment. The subject matters of physical and cultural geography are regarded by many as different entities, though recent research indicates that they have much in common. Realist epistemology, or knowledge of the world, may seem to be challenged by analyzing ontology for the limitations of its objectivity rather than for how we know phenomena through cultural and social ways. For subspecialties of cultural and physical geography to interrelate, new terms of discourse must be developed with established semantic meaning that can integrate realism and relativism. Faced with new biotechnologies, for example, writers look to ontology as a way to articulate natural subjects and their social factors, that is, the blurring of the boundaries between the natural and artificial (human-made) worlds.

The realism of ontology has been criticized as privileging materialism over semantic or epistemological relations, such as ethics. Ontology provides no groundwork for ethics, which is an experience of life. The elevation of political and social access to the level of ontology, that is, to a status of what seems to be naturalized or whose relative status is purposely concealed in the world, is the subject of critical geography.

Some geographies are organized and mediated by the expression of their ontologies through technology. In geographic information science and systems, for example, ontology is applied to the clarification of concepts and the integration of data, especially from heterogeneous sources, similar to standards that clarify ambiguous concepts and terms. The corporality of experience of geography, however, may be lost or is manipulated through technological practices, such as photography. It is important to recognize that technologies such as computerized code structure social relations through their relations to social, scientific, and cultural environments.

Several methods are used for developing conceptual ontologies, including building generalizations from detailed information such as texts of applications, extracting technical concepts from domain experts, or “reverse engineering,” a method by which the ontology is formed by automatically generalizing it from the source data. Rather than trying to devise a single ontology that encompasses a wide array of viewpoints, a series of ontologies with linkages between them may be advocated to reflect contexts with a series of articulated problems of the subject domain and their potential implications.

OPEN GEODATA STANDARDS

Geospatial data present unique challenges due to the complexity of the organization and storage of data concerning a broad array of spatial objects collected in different formats, with different reference systems. Geospatial data storage and transmission are complicated by the storage requirements of geospatial data (archives of multiple terabytes are common), by the need to store the location of features or imagery as well as information on their spatial reference system and associated metadata, and by the increasingly common requirement that data be accessible by multiple users from a range of different platforms. The Open Geospatial Consortium (OGC) has taken the lead in the development of open geodata standards. As defined by OGC, open standards are created in an open, participatory process that is technology neutral and in which the final specification is publicly available to all parties without royalties. Open standards provide a common, publicly available framework for the storage and transmission of geospatial data that ensures data access and service interoperability while allowing for the development of distributed geospatial applications.

Successful open geodata standards are important both for data management, by ensuring ease

of data access and archiving, and for the design of interoperable geospatial services. Lack of well-known, open standards complicates the integration of data from multiple sources when data from different sources are stored in different, proprietary formats. Conversion of geospatial data between alternative formats is often difficult due to the large storage requirements of geospatial data and the processing power needed for conversion, as well as due to the complexity of geospatial data formats. Open geodata standards allow interoperability of geospatial services without the necessity of data conversion, while also encouraging the reuse of data and program components in multiple applications with standardized interfaces.

Distributed geoprocessing and Internet location-based services require the interconnection of multiple software applications and data sets. Open geodata standards provide a common framework for data access and storage, allowing developers to build seamless applications. For instance, a user could use a Web application to access vector features from a range of Web sources conforming to the Web Feature Service (WFS) standard developed by the OGC to dynamically build a vector map. Without an established standard such as the WFS, interoperability of Web services would be problematic.

Open Geospatial Consortium

The Open Geospatial Consortium (OGC) is an international member organization that has coordinated and taken the lead in the development and dissemination of open geodata standards. The OGC operates by consensus of its member organizations to refine existing standards and to develop new standards as technologies evolve. The basic framework for the OGC body of standards is outlined in the OpenGIS Abstract Specification, which provides a conceptual model for the developing body of standards.

New OGC standards, as well as revisions to existing standards, are developed through the OGC Specification Program, a consensus process that allows members to comment on proposed standards through formalized committees. The OGC cooperates with other international standards bodies such as the International Standards

Organization/Technical Committee 211 (ISO/TC 211) in developing geodata standards. Several OGC standards have been adopted by ISO/TC 211, including the OpenGIS Simple Features Interface Standard (SFS), also published as ISO 19215, that specifies a common representation of features (such as points, lines, and polygons) within GIS systems. The SFS uses “well-known text” and “well-known binary” formats to represent the basic geometry of features. These open formats provide a common interface for software developers to exchange and store data that can be accessible in multiple applications. The standard also defines basic spatial operations, such as “intersects,” “contains,” and “overlaps,” to standardize geoprocessing procedures on these features.

The OGC has also developed a set of standards for Web services for accessing and displaying geospatial data on the World Wide Web. The Web Map Service provides a common framework for developers of Web applications returning maps in a raster format. The Web Feature Service provides for the return of vector data, while the Web Coverage Service provides a uniform standard for the return of raster data such as satellite imagery, or digital elevation models as coverages.

International Standards Organization/ Technical Committee 211

The International Standards Organization/Technical Committee 211 (ISO/TC 211) is the ISO committee responsible for the development and implementation of international standards concerning geospatial data. ISO/TC 211 oversees the development of the ISO 191** family of standards relating to the acquisition, management, transmission, and display of geospatial data. Though the work of ISO/TC 211 is not aimed explicitly at the development of open standards, it works closely with the OGC, and several standards have been concurrently adopted by both organizations.

ISO 19101:2002 outlines the Reference Model for the ISO 191** series of standards. The Reference Model describes the conceptual model by which conforming applications will interoperate and provides a framework for the ISO 191** series of standards. An important issue in geospatial data management and cataloging is the

appropriate use of metadata. To standardize metadata terminology, usage, and encoding, several ISO standards have been developed. ISO 19115:2003 and ISO 19139:2004 standardize metadata usage and encoding using well-known formats.

OPEN GEOSPATIAL CONSORTIUM (OGC)

The Open Geospatial Consortium (OGC) is a nonprofit international voluntary consortium of more than 370 private companies, government agencies, and academic institutions that develop publicly available, consensus-based interface specifications and interoperability standards for geospatial data. Interoperability—the ability of different systems to transparently exchange geospatial data—became a pressing concern to GIS users in the 1990s. To solve interoperability problems, the U.S. Army Corps of Engineers developed the open-source GIS software the Geographic Resources Analysis Support System (GRASS) in the early 1990s, but open systems by themselves did not prove to be a complete solution. Members of the GRASS community formed the OGC in 1994 with the vision of allowing users to access geospatial data created by others regardless of the software used.

Since its establishment, OGC has focused on developing standards for geographic information exchange. These standards are open, that is, they are technology neutral, developed by a participatory process, and with free rights of distribution.

The OGC develops standards by two methods. The Specification Program develops standards in a formal process requiring member approval. This program collaborates with the International Standards Organization and the Federal Geographic Data Committee. The Interoperability Program is a test bed activity in which a rapid, coordinated test is performed on a proposed interface standard in an open environment to refine solutions for OGC specifications.

The OGC has developed the Open GIS Abstract Specification, a suite of conceptual models to guide development of individual implementation specifications. The abstract specification includes topics such as spatial referencing, locational geometry, metadata, earth imagery, and so on. The OGC has released several widely adopted implementation standards that specify encodings for the request of raster coverages, features, and maps from distributed servers over the Internet. The OGC has also adopted Google's Keyhole Markup Language (KML) as a standard for users to create annotations and visualizations for online and mobile maps and Earth browsers.

The OGC has provided support for interoperability test beds, for example, a 2008 Canadian Geospatial Data Infrastructure interoperability project whose main objective was to test how open standards could improve collaboration among data producers and users from Canada's local, provincial, and national governments; nongovernmental organizations; and private companies.

Semantic interoperability, that is, a means for assessing the content and meaning of items encountered on the Web, is an important enabling technology for the next generation Internet. In 2006, the OGC conducted an experimental project on geospatial ontology and is developing an ontology framework and reference model.

OPEN-PIT MINING

Open-pit mining, also called opencast, open-cut, strip mining, or quarrying, is a mechanical extraction method that dates back to over 3,000 years. Ancient mines include the Tongling copper mine of China's mid Shang Dynasty 3,300 $\pm$ 60 years ago and some potential United Nations Educational, Scientific and Cultural Organization World Heritage sites—Mitterberg in Austria and the Timna mine from ancient Egypt (now located in Israel). Quarrying refers to opencast mining that extracts building materials, such as granite, limestone, marble, and slate. The method extracts resources occurring close to the surface or deeper formations that are structurally unstable or too friable to make tunneling possible. Commonly mined minerals include bauxite, copper, diamonds, gold, gypsum, kaolin, lead, manganese, nickel, phosphate, and zinc. The largest resource mined is coal, which also produces the greatest amount of solid waste.

With the rise of the Industrial Revolution, there was an urgent need for coal and iron ore, which fueled massive growth of mining. As technology

advanced, there was recognition that other metals could be of use, such as titanium, aluminum, and platinum. Peasant populations moving to cities to take advantage of new industrial jobs required greater coal extraction for electricity generation and iron ore for the building of urban infrastructure. Human wealth increased, creating a demand for gold and diamonds. As a consequence of this growth, mines expanded into huge operations, such as the Bingham Canyon copper mine in Utah, which is the largest excavation in the world, measuring 790 m (meters; 2,590 ft. [feet]) deep and 3.7 km (kilometers; 2.3 miles) wide. The mined-out, open-pit Big Hole diamond mine in Kimberley, South Africa, reached a depth of more than 1,000 m (3,300 ft.). Some of the largest opencast mines in the world are the Cerrejon coal mine in Colombia and the Grasberg-Erstberg copper mine in Indonesia, which extracts 0.24 million tons of copper ore every day.

Surface vegetation, soil material, or overburden covering the ore-bearing horizon is stripped off by earth-moving equipment, such as bucket wheel excavators, stripping shovels, and walking draglines. Rock material is broken up by explosives, and mechanical shovels separate minerals from gangue. Blasting may be preceded by drilling holes into rock to implant explosives. In coal mining in hilly terrain, overlying material is stripped following the contours around the hillside or removed off the mountaintop to expose the underlying coal seams. Deposits are mined along benches, steps, or terraces cut along the wall of the excavation. Minerals are transported by truck or train to undergo further processing. This may involve the use of chemicals such as in the cyanide leach process in gold mining. The method causes marked environmental degradation.

Environmental effects of open-pit mining include erosion, sedimentation, and landslides. It has been estimated that solid waste produced by metal mining is 8,000 million tons/year. The "shoot-and-shove" mining practices of coal mining in the Appalachian Mountains of the United States have caused widespread environmental devastation. The rock overburden above the coal seams is blasted away and then pushed into the valleys, infilling streams, and destroying river ecosystem. Hydraulic mining, in which high-pressure water is aimed at hillslopes to loosen the sediments

in which the gold is contained, is commonly practiced in gold mining in developing countries. This technique leads to unstable hillslopes and enhanced erosion and sedimentation of nearby streams. Tailings from gold ore processing end up in artificial ponds and may be toxic due to the use of hazardous chemicals or associated gangue minerals such as arsenopyrite (see the second photo). Mercury is also commonly used in the extraction of gold, and approximately 3,000 tons of this toxic chemical has found its way in the past 15 years into the Amazon River due to mining activities. This has led to contamination of the environment, and biomagnification and bioaccumulation increased the toxicity of the mercury for the wildlife in the basin.

The Red Dog mine in Alaska is by far the largest producer listed in the U.S. Environmental Protection Agency's (EPA) Toxic Release Inventory (TRI) with 615 million lb. (pounds). It is the largest zinc mine in the world and a significant source of lead production. The six largest producers

listed by EPA on the TRI are all mining operations (102–144 million lb.). The largest superfund site in the United States is the Yankee Doodle tailings pond in Montana, with a 600-ft.-high tailing pond dam, the result of copper mining in the state. Church Rock Mine in Arizona released 94 million gallons of slurry (pH 1.6) containing radon, thorium, and uranium into the Peurco River in 1979. On the day of the spill, the river had 13,000 pc/L (picocuries/liter), when the recommended limit for drinking water is 30 pc/L. The Grasberg-Ertsberg mine in Indonesia dumps 0.2 million tons of tailings into the Ajkwa River every day, causing aggradation of the coastal floodplains.

Human health effects are related to breathing in airborne particulates generated during extraction or toxic waste leaching into drinking-water supplies. The particulates (less than particulate matter 10 [$<PM_{10}$]) from coal mining can lead to respiratory illnesses such as asthma in

Tailings pond at the St. Elizabeth Gold Mine, Mahdia, Guyana, in 2009

Source: Fenda A. Akiwumi.

small children, although little research exists on this matter. Heavy exposure to coal dust has been shown to lead to black lung for miners. Mercury forms an amalgam with gold, and miners burn off the mercury, thereby breathing in the vapors leading to Minamatta Disease.

Mining companies are expected to prepare environmental impact statements prior to mining and land reclamation to rehabilitate land destroyed by mining. Both areas are not adequately addressed in mining ventures worldwide. Federal legislation such as the Surface Mining Control and Reclamation Act of 1977 in the United States, for example, requires reclamation of surface lands affected specifically by coal mining operations but not other forms of surface mineral extraction. The high cost of rehabilitation strategies and resources to ensure enforcement of laws and regulations prohibits effective enforcement.

OPEN SOURCE GEOSPATIAL FOUNDATION

The Open Source Geospatial Foundation (OSGeo) is a U.S.-based not-for-profit organization that supports and promotes the use and collaborative development of open-source geospatial technologies and data around the world. OSGeo offers marketing, financial, organizational, and legal help for its projects. The mission includes advocacy and marketing and encourages the development of

business models based on Open Source GIS (OSGIS). The foundation acts as an advisory body for OSGIS software projects as well as educational material and public geospatial data development projects. Communication is based on classical methods and newer Web 2.0 tools: Wikis, issue trackers, mailing lists, Web sites, Internet Relay Chat, and blogs.

History

OSGIS-related user and developer communities have existed since the early 1980s. They expanded significantly with the advent of Internet and electronic communication. Each relevant OSGIS project had its own community, in most cases only in virtual form and without formal structures. In response to the increasing need of collective support of OSGIS software development efforts, the Open Source Geospatial Foundation was officially created in February 2006 as a not-for-profit organization.

OSGeo Projects

OSGIS-related software projects that want to become part of the foundation have to undergo an incubation phase to verify if the project conforms with OSGeo principles. Accepted projects demonstrate mature project management, with open and collaborative development and user communities. Increasingly, real-time code quality assessment systems are implemented. A review of the intellectual property of source code and documentation has been performed. OSGeo software projects include geospatial-programming libraries, desktop GIS, Web mapping/WebGIS, and metadata catalogs.

In addition to software dissemination, OSGeo aims at educational outreach. Part of the mission is to promote OSGIS training among universities and other educational institutions; OSGeo is preparing and providing training materials and teaching support released under free licenses.

Third, OSGeo promotes the use of open geospatial data formats and public access to state-collected geospatial data. In collaboration with other entities, licenses for public geospatial data are developed with adaptation to various legislations.

OSGeo Governance

OSGeo is a community-driven and distributed organization with a formal seat in the United States but legal components distributed in various countries. It consists of an elected board of directors, an executive director, elected charter members (eligible to vote for the board), and members-at-large. The members collaborate through various projects, committees, and local chapters, which represent OSGeo around the world in different countries and language groups. All projects are managed through individual project steering committees (PSCs) with PSC chairpersons serving as foundation officers.

OSGeo annually presents the Sol Katz Award for Geospatial Free and Open Source Software (GFOSS) to individuals who have demonstrated leadership in the wider GFOSS community. Recipients of the award are recognized for their significant contribution in the geospatial realm to advance open-source ideals.

Since the early days of OSGIS communities, annual conferences at national and international levels were organized. In 2006, OSGeo merged several of their community events into the “Free and Open Source Software for Geoinformatics” (FOSS4G) conference series, which is hosted each year in a different country. In addition to the common conference scheme, these conferences include a 5-minute plenary, “Lightning Talks,” and “code sprints,” where project teams get together for valuable face-to-face planning and concentrated programming time.

OPEN SOURCE GIS

Open Source GIS (OSGIS) is a family of GIS software packages that are published along with their respective source code, in contrast to the closed-source model of proprietary GIS packages. Usually, open-source software is understood to be also free software, that is, the source code is published under a free software license with the rights to run the program for any purpose, to study how the program works, to adapt it, and to redistribute copies, including modifications. These software licenses, including the license-free public domain, are evaluated and promoted by the Free Software Foundation (FSF, www.fsf.org) and the Open Source Initiative (OSI, www.opensource.org). OSGIS is the general concept of Open Source/Free Software applied to GIS software.

History

Software Projects

GRASS (Geographical Resources Analysis Support System) is the earliest OSGIS, which reached production status and supported both raster and vector data. It was originally developed from 1982 to 1995 by the U.S. Army Corps of Engineers and since then by the international GRASS Development Team. Initially published as public domain software, its license was changed to GNU GPL (General Public License; see www.gnu.org) in 1999, one of the commonly used Free Software licenses. The GPL ensures that modified or new source code must be published again under the GPL. In the 1990s, further desktop and server OSGIS software projects were established in various GIS sectors, including libraries (PROJ4, GDAL/OGR, GEOS, Geotools, Geoserver), Desktop GIS (Quantum GIS, SAGA GIS, uDIG, gvSIG, ILWIS), Web mapping/WebGIS (Mapserver, MapGuide Open Source, degree), spatial SQL (Structured Query Language) databases (PostGIS), geostatistics (gstat, R Project for Statistical Computing), and metadata catalogs (Geonetwork opensource).

Organizations

In 1992, several organizations were merged into the Open GRASS Foundation (OGF) with

the scope to expand private sector developments for GRASS, to manage memberships, and to recruit sponsors from government, the private sector, and academia. The spread of GIS raised the need for data sharing and interoperability. With more industrial companies joining, OGF was restructured as the Open Geospatial Consortium (OGC) in 1994 with a focus on interoperability and geospatial standards.

The increasing number of OSGIS projects led in 2006 to the creation of the Open Source Geospatial Foundation (www.osgeo.org), whose mission is to support and promote the collaborative development of open geospatial technologies, data, and educational material.

Philosophy, Development Methods, and Community

Open Source in general refers to a software development method where the source code is maintained in a public repository with a group of developers, often volunteers, working on it. After peer review of code style, functionality, and quality, software packages are regularly released under a commonly accepted software license that regulates the distribution terms ensuring free redistribution, permission of modifications and derived works, and more (see “The Open Source Definition,” www.opensource.org/docs/osd; “What Is Free Software and Why Is It So Important for Society?” www.fsf.org/about/what-is-free-software). For the end user, the promise of Open Source is to receive quality software at lower cost, which is flexible, interoperable, and free of any vendor lock-in. OSGIS software packages are developed following this philosophy. Open source software can be considered commercial like proprietary software as it is also used in commercial projects by for-profit companies offering a variety of related services.

The important OSGIS software packages are interoperable and follow industrial standards for data exchange. The geospatial industry has started to integrate OSGIS libraries into their proprietary products to improve their interoperability capabilities. Additionally, and in contrast to dominant proprietary GIS software packages, OSGIS are portable, that is, they can be operated on various computer operating systems.

OSGIS is strongly linked to the opening of the Internet to the civil society and the subsequent availability of collaborative development tools and means of electronic communication. Through this, virtual developer and user communities were formed, which strongly support the evolution of software and its documentation. In some cases, companies are also involved, even pursuing the development as the main actor.

Functionality

The relevant OSGIS software packages offer functionality comparable with proprietary GIS. As in the traditional industrial market, general-purpose tools and specialized applications are available.

Available OSGIS libraries include reprojection support, optimized spatial data storage (nontopological/topological, with integration in spatial SQL databases), and data exchange in all common and also special spatial formats. Open Source Desktop GIS offer a graphical and sometimes also command line access to spatial algorithms, including import/export of common GIS data, from GIS Web services and from global positioning systems with scopes for risk analysis and assessment, map projections, raster and vector network analysis, spatialization, and geovisualization. Processing of digital terrain model data, creation of flow maps, geocoding of raw data, map generalization, terrain analysis, viewshed analysis, as well as map algebra are supported. Vector data can be generated through digitizing from scanned paper maps or through vectorization of raster data; some OSGIS also support the analysis of topological relationships. Geostatistics are either found in dedicated software packages or through dedicated GIS interfaces to spatial classes of statistical software, which directly read from the GIS database. Further functionality includes image processing with data extraction from LiDAR (light detection and ranging) and airborne laser scanning, analysis of microwave/RADAR (radio detection and ranging) data, multispectral imagery, multitemporal imaging, stereoscopy and orthoimagery, and supervised classification of aerial and satellite data. Reduced and optimized software packages are available for mobile GIS.

Open Source Internet GIS is provided as passive Web-mapping applications or as interactive

WebGIS with the capabilities of a Web processing service.

For OSGIS metadata management, dedicated catalog systems are available, which operate as online metadata harvester and retrieval systems. They access and list spatial data hosted in-house or in remote but Internet-accessible databases through specialized protocols for metadata exchange.

OPEN SPACE

Open space has many meanings, at multiple and overlapping spatial scales. Globally and regionally, it may refer to the extent and condition of significant biomes, such as tropical forests and deserts. A more limited definition would include only protected areas, such as parks and nature preserves. Worldwide, according to the International Union for the Conservation of Nature, 11.6% of the globe's terrestrial surface area is protected, though a great deal more of the world's land consists of vast areas of farmland, forest, desert, grassland, tundra, and snow and ice. Typically, though, the term *open space* applies to amenity-rich lands in industrialized countries and to a lesser degree to minimally developed lands in poorer countries. Often, these open spaces are in contested areas, where development pressures lead to concerns about loss of valued open spaces.

Open-space protection and management is a vital concern, for example, in both the New York

Aerial view of Central Park in New York City. Most open spaces are largely free of industrial, commercial, and residential development and are readily accessible to the public.

Source: iStockphoto.

and Shanghai metropolitan regions. New York seeks to protect watershed and agricultural lands, while Shanghai is concerned with expanding its urban greenbelt. In the United States, and across the globe, open-space management must contend with complex questions of spatial and intergenerational equity, agricultural sustainability, housing affordability, cost-effectiveness, and ecological integrity. This entry examines the values that underlie efforts to protect and manage open space and then describes approaches to open-space protection and management through regulation, purchase of open space, and collaboration.

Definitions and Values

Definitions of *open space*—sometimes referred to as *greenspace*—vary widely, ranging from urban

parkland to wilderness areas and water bodies. Most open spaces are largely free of industrial, commercial, and residential development and are readily accessible to the public. Sometimes, that access is simply visual access—as in the case of scenic vistas of privately held, entry-restricted farmland or woodland. Generally, open space is available for various types of active recreational use, and often there are conflicts over the environmental appropriateness of different uses. In the United States, with its extensive areas of open space, environmentalists tend to favor low-impact uses, such as hiking, biking, canoeing, and cross-country skiing. Conflicts frequently arise over competing demands for recreational uses—with soccer and ball fields, equestrian trails, mountain biking, and off-road vehicles often at the center of controversy. Increasingly, the value of recreational open spaces in combating America's

obesity epidemic is being promoted. Beyond their recreational values, open spaces can act to protect streams and watersheds, provide habitat for flora and fauna, function as corridors and patches in local and regional open-space networks, and sequester carbon.

Several approaches to open-space protection and management are employed.

Regulatory Approaches

Open space can be protected very effectively through regulation. Governments can restrict or prohibit development on specific lands while permitting it in places deemed environmentally and otherwise appropriate. Strong regulatory approaches, aimed at concentrating development and limiting sprawl, are especially common in Europe.

In the United States open-space regulation is complex and highly contested, with most of it taking place at the local level, in the form of municipal and county master plans, combined with zoning and subdivision requirements. Open space is preserved, in varying degrees, by local regulatory schemes, as well as market forces that simply do not support development in particular places. State- and regional-level regulatory schemes are less common, though states such as Oregon, with its imposition of urban growth boundaries; Vermont, with its statewide land use regulatory plan; and New York and New Jersey, with regional regulatory plans for the Adirondack Mountains and Pinelands, respectively, are widely viewed as leaders.

Purchase of Open Space

Land acquisition is deployed widely in the United States by governments and nongovernment organizations. Created in 1965, the federal Land and Water Conservation Fund (LWCF) provides funds for federal, state, and local land acquisition. But congressional funding allocations under LWCF have been highly inconsistent and often very meager. Additional federal support for land acquisition comes from a raft of federal programs, including the Forest Legacy Program, the Transportation Enhancement Act and Transportation

Equity Act, and legislation supporting trails, river protection, and heritage area management. Most states have their own funding programs; indeed, densely populated states support the most robust efforts, as is the case with New Jersey's Green Acres program. Municipal and county governments—particularly in the fringes of metropolitan regions, where sprawl pressures are high—have allocated substantial funds for land acquisition. Between 1988 and 2008, as detailed in The Trust for Public Land's database, voters approved a total of 1,611 ballot measures, authorizing more than US\$112 billion for various land protection efforts. Critics of acquisition point to its high costs and argue that it does not necessarily ensure permanent protection.

Collaborative Approaches

When the Reagan presidency ushered in an era of greatly restricted government, collaborative land management approaches became imperative in the United States. Nonprofit land trusts, which have proliferated since the 1980s, buy lands and secure conservation easements, which restrict or prohibit development. Land trusts can act more quickly than governments and often purchase lands or easements that are later transferred to public agencies. Watershed conservancies are also active locally, as land managers and conservation advocates. States and localities support these diverse local efforts with various grant and incentive programs, as do the federal efforts noted above. Most states and many localities have farmland protection programs. "Smart-growth" programs, increasingly popular in recent years, deploy a set of traditional, mostly incentive-based planning techniques to concentrate development in and near urbanized regions while protecting open space and promoting affordable housing. Maryland, Pennsylvania, New Jersey, and Oregon are among the smart-growth leaders.

Given the limited availability of funds and the high costs of acquisition, governments seek to expand their capacity to protect lands through collaborative approaches. Though collaborative approaches are widespread in the United States, they encounter strong opposition from "wise-use" and property rights groups, as well as some

environmental organizations that feel government is abdicating its land management responsibilities.

ORGANIC AGRICULTURE

Organic farming is defined as producing crops without the use of synthetic chemicals in insecticides, herbicides, or fertilizer; instead, farmers rely on their knowledge of their land and soil conditions to devise their ecological farming techniques. They use many types of natural and alternative methods, such as planting two or more companion crops together so that they protect each other from pests, using green manure (which is a crop that is tilled into the soil to provide natural compost), and breaking the chain of pests by rotating crops (growing different crops in succession on the same plot of land). In addition, crops themselves tend to be more varied and diverse, so that the farmer need not depend on the success of one single monocultured crop. Instead of growing

just corn or perhaps corn and soybeans, an organic farmer may grow corn, soybeans, wheat, buckwheat, alfalfa, other vegetables, and fruits for example. In the past two to three decades, the demand for organic food has grown immensely, especially in Europe and North America.

Certified organic farming in the United States is regulated through the U.S. Department of Agriculture (USDA), which established National Organic Standards that became effective in 2002. A quick reference point to remember is being chemical-free for 3 yrs. (years). A farm may not use prohibited synthetic substances for 3 yrs. prior to certification. The USDA National Organic Standards Program accredits numerous agencies across the country that act to administer the certifications in different states. This involves on-farm inspections, careful details of farm history, written proof of procedures and methods, and detailed notes about each crop. The farmers must pay for annual certification. The certification allows farmers to sell their products more widely at the national or even international level.

Since the mid 1980s, the U.S. organic food market has increased 20% annually. This is the fastest-growing sector of food consumption. Most people remember when few organic items were available in mass-market superstores, but that has certainly changed. The year 2000 marked the first year when more organic foods were sold in mainstream supermarkets than in any other venue. In fact, nearly 80% of conventional grocery stores now carry organic food items. Organic food sales are led by fresh produce, nondairy beverages, breads and grains, packaged foods, and dairy products. Organic dairy items increased by 500% in the 1990s, as a result of consumers seeking to avoid recombinant bovine growth hormone (rBGH), a genetically engineered hormone injected to increase milk production in conventional dairy cows. Since milk is not labeled in most countries, there may be no way to avoid rBGH unless one buys organic milk, in which its use is prohibited. Consumer demand for all organic products is likely linked to consumer concerns about pesticide residues and genetically modified organisms (GMOs) in food. Indeed, several studies show significantly lower pesticide residues in organic compared with conventional food. Parental concern about food safety often

motivates parents to buy organic food for their children. Recent studies show that children who eat organic food have significantly lower levels of pesticides in their urine. The Environmental Working Group Web site used 43,000 samples to develop a list of the produce with typically higher and lower chemical residues.

Organic food labels help inform consumers about the products they purchase. Foods that meet certain requirements are allowed to display the “USDA Organic” seal. There are three designated categories for items containing organic ingredients: (1) Products labeled “100% organic” contain only organically produced ingredients. (2) The “organic” label indicates products that are at least 95% certified organic. (3) The “made with organic ingredients” label is for items with at least 70% organic components. A food item containing less than 70% organic ingredients may not be marketed as an organic food.

While farmers may use organic methods, only the certified farmers may label their products as such. So some farmers opt to use similar terms: “ecological,” “natural,” or “pesticide-free.” These may be organic food products but without certification. Farmers who sell directly to consumers build up trust and may not need certification. Direct marketing is extremely important for many organic farmers, and this includes farmers’ markets, farm stands, U-pick farms, and farms established through the Community Supported Agriculture membership. These allow consumers to have a close relationship with the person who grows their food, and these personal ties often transcend the need for any official certification.

Today, organic agriculture is modern, popular, and profitable. While historical images of organic farming convey an image of hippies and

Organic farmer Phil Foster (*left*) and horticulturist Eric Brennan inspect leaves of red chard on Foster’s diverse organic farm in San Juan Bautista, California.

Source: Scott Bauer/Agricultural Research Service, USDA.

an alternative lifestyle, now efficient organic farms represent an opportunity for farmer families to make agriculture profitable.

ORGANISATION FOR ECONOMIC CO-OPERATION AND DEVELOPMENT (OECD)

The Organisation for Economic Co-operation and Development (OECD) is an international forum for the coordination of economic and environmental policies among most (but not all) of the world's largest economies. Its mission is to help policy-makers facilitate economic investment, growth, and trade among member states, maintain financial stability, enhance democratic governance, and promote market-oriented development. Other goals involve fighting corruption, monitoring corporate abuse, enhancing transparency, and improving public administration. At times, it is a forum for the application of international moral suasion.

Founded as the Organisation for European Economic Co-operation in 1948 as part of the post-World War II endeavor to administer the

Marshall Plan funds, it became the OECD in 1961. It is headquartered in Paris. As the number of member states grew, reaching 30 at present (Figure 1), it incorporated non-European countries as well. Today it includes most of Europe, Turkey, the United States, Mexico, Canada, Japan, South Korea, Australia, and New Zealand. Given that these countries collectively dominate the world's economy, the OECD exerts an important influence over much of the planet. Another 25 countries have observer status, and the organization has working relations with 70 others. The OECD also maintains relations with various labor unions and nongovernmental organizations.

The primary role of the OECD is to facilitate flows of information among its member states. It has been called a *think tank*, monitoring agency, and “nonacademic university.” Toward that end, it collects internationally comparable statistics, publishes books and articles on numerous topics, issues guidelines and forecasts, monitors trends, and hosts an annual meeting in which 40,000 delegates attend. It also has a series of secretariats, directorates, and centers oriented to specific issues such as education, health care, energy, agriculture, labor and employment, technological change, fiscal policy, taxation, and so on. Representative examples of recent analyses include bio-fuels, global climate change, reforms of troubled financial markets, immigration and the globalization of labor markets, aging workers, uses of nanotechnology, the digital divide of Internet access, spam minimization, and offshore tax evasion. The goal of such efforts is to identify best practices, compare policy experiences, and find answers to common problems. Although its role is largely advisory, the information it collects and produces frequently enters into international agreements and dispute settlements, as well as academic research. Its annual budget of roughly a half billion U.S. dollars is funded by member states and reflects the size of their relative gross domestic product.

Critics of the OECD allege that it shares common neoliberal goals with similar groups such as the International Monetary Fund, World Bank, and World Trade Organization, that is, the promotion of deregulated markets that favor a few at the expense of the many.

Barney Warf

ORGANIZATION OF THE PETROLEUM EXPORTING COUNTRIES (OPEC)

The Organization of the Petroleum Exporting Countries (OPEC) is a cartel of 12 major oil-producing nations that was founded in September 1960. Occasionally, there are economic arrangements whereby several interdependent firms in an industry collude to set prices, output, and market share for their product or products. When this arrangement is established formally and openly,

it is called a *cartel*. While such an agreement would violate antitrust laws in the United States and other countries, because OPEC operates in international petroleum markets it is able to produce and sell oil in this manner, subject to short-term market conditions. OPEC has maintained its world headquarters in Vienna since 1965. Its ability to control international petroleum markets has varied over time, depending on demand, prices, reserve margins, and the perceived or real scarcity of oil. This entry reviews the member states, functions, and operations of the OPEC cartel, along with highlights from its 50-year history. OPEC's long-term stability is also addressed.

There are several advantages to an oil cartel. These include increased profits to the member countries and their national oil companies, decreased market uncertainty, increased price stability, and the ability to prevent entry by an unwanted competitor. It should be noted, however, that the number of member nations in OPEC has changed several times in the past two decades, and efforts to recruit Mexico and Norway as permanent members have been unsuccessful. Many economists have argued for several decades that the structural conditions of the cartel are inherently unstable, and there is incentive for some members to cheat by secretly lowering their oil

price to increase market share. Alternatively, a firm could leave the arrangement and charge less in the open market to accomplish the same goal. While such behavior has occurred among a few OPEC members, especially during the period of low oil prices in the mid to late 1980s, OPEC remains alive and well in the 21st century—its members control two thirds to three fourths of the world's proved oil reserves (though only 35%–40% of production). Moreover, demand growth for oil seems unabated, and many observers have suggested that global oil production will soon peak, if it has not already.

Member States, Functions and Operations

The original members of OPEC were Saudi Arabia, Iran, Iraq, Kuwait, and Venezuela. Between 1961 and 1975, eight other nations joined: Qatar, Indonesia, Libya, United Arab Emirates, Algeria, Nigeria, Ecuador, and Gabon. Saudi Arabia is the largest producer and controls most of the proven reserves (both for OPEC and worldwide). Somewhat consistent with economic theory, membership in the cartel has changed several times: Ecuador and Gabon left in 1992 and 1994, respectively, out of concern over the high membership fee (US\$2 million) and to expand their oil production from what was allowed by OPEC; and Indonesia withdrew at the end of 2008, having become a net oil importer and unable to meet its production quota. However, Ecuador rejoined in November 2007, and a new member, Angola, had earlier joined on January 1, 2007. In addition, Russia and Norway joined as nonpermanent members in early 2000, and other oil producers have considered joining, including Brazil, Bolivia, and Sudan.

OPEC operates under a statute that was agreed to on its formation. The oil ministers of member countries meet twice per year at the OPEC conference to determine how best to stabilize oil markets and the means to advance their interests, individually and collectively, especially the achievement of a reasonable rate of return on their investments. This has been implemented through the setting of prices and excise taxes on crude oil sales and allocation of production quotas (though Iraq has not been part of the quota agreements since March 1998). The member countries also meet periodically to discuss other matters. In some cases, OPEC will raise or lower its collective output, or that of

an individual member such as Saudi Arabia, between the ministerial meetings if it believes that oil prices are too high or too low.

History

OPEC was not formed overnight. Its origins can be traced to a 1949 meeting initiated by Venezuela to increase regular communication among the major oil producers outside the United States. The United States was the dominant global oil producer at the time, though by 1948, it began to import more oil than it exported, mostly cheap Venezuelan crude. The most accessible U.S. oil fields would be exhausted in the 1950s and 1960s. Ironically, in this environment, many large oil exporters saw their revenue streams decrease. This occurred because the U.S. oil majors lowered prices in 1959, leading to declining royalty payments on sales from foreign oil producers. More important, U.S. Presidential Proclamation No. 3279, issued by Dwight Eisenhower on March 10, 1959, established a system for granting licenses to import oil and petroleum products under the Mandatory Oil Import Program. This action forced import quotas on Venezuelan and Persian Gulf oil in favor of Canadian and Mexican sources. As a result, the five countries that would become the OPEC met in Cairo in April 1959 and in Baghdad in September 1960 and formed the cartel as a means to increase the price of oil produced on their soils. The founding members were given veto power over the admission of new members. The initial reaction of the West was skepticism regarding the ability of OPEC to influence or control oil markets, and the cartel was in fact weak until the 1970s.

A series of changes in economic and political factors in the 1960s strengthened the OPEC. These included changes in the tax system, such as increases in the excise and income taxes levied on foreign oil companies operating in OPEC nations; crude oil price increases; the separation of royalty payments from income taxes; and a reduction in deductions allowed for oil companies. A further strengthening of OPEC occurred through members nationalizing a share or even 100% of concession agreements that had previously been granted to foreign oil companies.

The political environment also gradually changed in favor of OPEC in the 1960s. First, in

the area of decolonization, Kuwait, Algeria, Nigeria, and Gabon gained independence from the United Kingdom and France in the early 1960s. Second, Israel's victory in the Six Day War against Egypt, Syria, and Jordan in June 1967 angered the Arab nations and led to the formation of the Organization of Arab Petroleum Exporting Countries as a separate, somewhat overlapping group to OPEC, which included Egypt and Syria. The culmination of these actions and events was an oil embargo by the Arab oil producers against the United States, the Netherlands, and a few other supporters of Israel from October 1973 through March 1974. Thus, the "oil weapon" was unleashed for the first time in history. Widespread panic buying, fuel shortages, and government misallocation of supplies ensued in the United States and other Western nations and Japan, which scrambled to find alternatives to imported oil.

OPEC held its greatest economic and political power from 1970 until 1986. This status can be attributed to several factors: Its largest single customer, the United States, experienced a peak in domestic oil production in 1970 and became increasingly reliant on imports; the 1973–1974 oil embargo demonstrated OPEC's considerable political muscle; a vast increase in oil revenues flowed to the OPEC nations, following an initial quadrupling in prices by 1976, plus even larger price increases in the chaos following the 1979 Iranian Revolution. Due to perceived shortages of oil, and especially more panic buying, real prices rose to record highs in 1981 (unsurpassed until 2007–2008). With the record oil prices in the first half of the 1980s, consuming nations switched away from oil-fired power plants, built and purchased more energy-efficient motor vehicles, and implemented many other conservation measures. Additionally, alternative sources of oil came on stream, including the North Sea (principally Norway and the United Kingdom), Russia, Mexico, Canada, and China, although North Sea production has been declining since 2001. Consequently, the demand for OPEC oil fell precipitously, leading to a drop in oil prices in 1986 by almost half (prices would not recover until 2000). By then, Iran was mired in a lengthy war with Iraq for regional dominance, and OPEC appeared to be in disarray.

Since the late 1980s, several OPEC members have been preoccupied with various wars, especially

Iraq. During this time, oil prices have been generally low, before the price spikes of 2007–2008. Not long after Iraq and Iran ended their 8-yr. (year) battle in 1988, Iraqi forces invaded and occupied Kuwait in August 1990, in apparent payback for Kuwait not forgiving Iraq's considerable debt amassed during its war with Iran. This, in turn, led to the U.S.-led international coalition fighting the Persian Gulf War with Iraq in early 1991. Following a lull of 12 yrs., the United States spearheaded an invasion of Iraq in 2003 (and officially claimed that the invasion was not about oil), and combat troops are still there as of 2009–2010. Despite these conflicts, the OPEC has been able to effectively maintain its function of price setting and allocation of production quotas to members, though some observers have deemed it ineffective and irrelevant. However, member nations of OPEC still control at least two thirds of the world's proved oil reserves, and a transition to alternative energy sources has been slow.

Long-Term Stability

Questions remain about OPEC's long-term stability. As noted, Iraq was at war with Iran and Kuwait in the 1980s and early 1990s, respectively. In addition, Algeria and Angola had civil wars from 1991 to 2002 and from 1975 to 2002, respectively. Given other differences between member nations, it is probably in the best interest of some countries to keep oil prices low, while others may prefer high prices. For example, a country with extensive proven oil reserves would prefer moderate prices to sustain long-term sales to major consuming nations, since high oil prices stimulate energy conservation and the development of alternative energy sources. Conversely, OPEC nations with modest reserves may prefer higher prices. Members with large reserves include Saudi Arabia, Iran, Iraq, Kuwait, United Arab Emirates, and Venezuela, while Ecuador, Angola, and Algeria have small reserves (Table 1). As for population, the more populous member nations may prefer high prices to fuel a larger economy; members in this situation include Nigeria and Iran. In the case of income levels, member nations with a low gross domestic product (GDP) per capita may also prefer higher prices to decrease poverty in their countries. On this dimension, Nigeria, Iraq, Ecuador, Angola, Algeria, and Iran would seem to prefer higher

Country	Population (in millions)	Oil Reserves (in billions of barrels)	GDP per Capita (US\$)	External Debt (US\$ billion)	% GDP
Nigeria	148.2	36.22	1,126	8.0	2.7
Iran	70.4	136.15	4,179	20.7	2.7
Algeria	33.5	12.20	4,037	4.0	1.8
Iraq	29.0	115.00	1,935	100.9	98.5
Venezuela	27.5	99.38	8,416	43.3	13.0
Saudi Arabia	24.3	264.21	15,478	58.6	10.7
Angola	17.0	9.04	3,602	8.4	8.8
Ecuador	13.6	4.66	3,282	17.1	17.3
Libya	6.2	43.66	9,260	4.8	6.5
United Arab Emirates	4.4	97.80	43,803	61.7	37.5
Kuwait	2.9	101.50	38,925	33.6	24.0
Qatar	0.9	15.21	75,426	33.1	46.3

prices. Finally, in the case of external national debt, member nations with high debt levels and debt as a percentage of GDP would seem to prefer higher prices in order to help pay off their debts. This would especially be the case for Iraq. To summarize, OPEC nations that would appear to be most interested in higher prices include Iraq, Nigeria, Algeria, Angola, and Ecuador, while nations that would appear to be most interested in lower prices include Saudi Arabia, Kuwait, United Arab Emirates, and Venezuela, with the interests of Iran, Libya, and Qatar less clear.

ORGANOPHOSPHATES

Organophosphates are a group of synthetic organic chemicals with some common elements in their chemical structure and the same toxic mechanism of acute toxicity. The general structure of organophosphates is characterized by a central phosphorus atom that is attached to an oxygen or a sulfur atom by a double bond and to three side chains by single bonds.

Organophosphates are mainly used as nerve gases and agricultural pesticides. In fact, organophosphate insecticides are the most extensively used pesticides for insect control in the world today. Organophosphates are also widely present in many commonly used products in modern life, such as solvents, plasticizers, flame retardants, gasoline additives, and therapeutic drugs, in both human and veterinary medicine.

All organophosphates have the same mode of toxic action for insects and mammals and can affect the nervous system by inhibiting acetylcholinesterase, an enzyme that degrades the neurotransmitter acetylcholine. Inhibition of acetylcholinesterase can result in excessive accumulation of acetylcholine at the synapses and neuromuscular junctions causing overstimulation of nerve cells. The nerve transmission will continue indefinitely and produce numerous symptoms, including slurred speech, loss of reflexes, weakness, fatigue, vomiting, headache, tremors, and eventually paralysis of body extremities and respiratory muscles.

Although some organophosphate compounds were described and synthesized in the late 1800s, organophosphate insecticides were first synthesized by Gerhard Schrader in Germany in the late 1930s and were brought to the market in 1940s. The toxic properties of organophosphates have also made them suitable agents to be developed as chemical warfare weapons. Several organophosphate compounds were developed as nerve agents and manufactured in significant quantities in Germany during World War II. However, organophosphate-based chemical weapons have rarely been used during warfare. One possible organophosphate-poisoning event in relation to war is Gulf War syndrome. After the end of the 1991 Gulf War, the U.S. and U.K. governments have conducted many studies on Gulf War veterans' illnesses. On November 17, 2008, a U.S. congressionally mandated research advisory committee has concluded that Gulf War veterans' illnesses are likely linked to exposure to neurotoxins, including a drug administered to protect troops against nerve gases and pesticides that were used against sand flies and other pests during deployment. In fact, nerve gas attack on the Tokyo subway can be considered the most well-known organophosphate-based chemical weapon event. On the morning of March 20, 1995, the Aum Shinrikyo cult carried out a sarin attack on the Tokyo

subway. This attack killed 12 people and injured more than 5,000.

Despite their high toxicity to human and wildlife health, organophosphates can break down more rapidly in the environment and persist from only a few hours to several months. Organophosphates were promoted as an attractive alternative to replace persistent organochlorine insecticides during the 1960s and 1970s. The use of organophosphate insecticides increased substantially after many organochlorine insecticides, such as DDT (dichlorodiphenyltrichloroethane), aldrin, and dieldrin, were banned in 1970s. Based on the Food Quality Protection Act of 1996, the U.S. Environmental Protection Agency has suggested that organophosphates pose the greatest risks to human health and the environment among currently used pesticides.

ORIENTALISM

Orientalism, as an area of study, has multiple definitions: It is an academic field that seeks to study *the Orient*, as well as a term for a more general interest in all things “Oriental.” However, within geography, it is most frequently employed as a critique of these two definitions. This critique of Orientalism was first extensively developed by the famed Palestinian scholar Edward Said (1935–2003). Orientalism in this context refers to the process by which “the Orient” (the area of the Middle East, as understood by Said) has been represented in particular ways by “the Occident,” or “the West” (generally understood to be Europe and the United States), both historically and in the

present day. Orientalism reflects, and works to maintain, the political and cultural power relationships inherent in colonialism and imperialism. Within Orientalism, “the Orient” is characterized as barbaric, primitive, passive, stagnant, and feminine, while “the West” is held in direct contrast, as rational, dynamic, progressive, and masculine. These totalizing representations are not the result of individual representational constructions but can be viewed within a broader, intertextual body of literature and other texts.

This entry begins with a detailed examination of Said’s *Orientalism* (1978). As with most widely discussed ideas, Said’s review of Orientalism has a number of critiques from a diverse community of scholars. These critiques include the combination of Said’s humanism with Foucault’s anti-humanism and the problematic methodological result of this combination. Critics have also taken issue with the impossibility of escaping from the very binary that Said highlights within Orientalism, as well as his inattention to gender and sexuality within Orientalist discourse. The entry concludes with a brief synopsis of the ways in which Orientalism has been taken up by geographers within subfields of geography.

Exploring *Orientalism*

Said was influenced by a number of scholars, including Jacques Derrida and Frantz Fanon, but methodologically drew from the French philosopher Michel Foucault’s concept of discourse analysis. Said’s critique of Orientalism used this method to show how the colonization of the Orient had been enabled and justified through Orientalist discourse. While Foucault contended that the individual author was virtually insignificant in creating discursive formations, Said aimed to expose the dialectic between the author and the overarching discursive body. The texts that Said examined were primarily those of high culture from the West (largely art and literature) but united a number of seemingly disparate spheres such as policy, academic knowledge, and popular cultural production. Through his analysis, Said sought to explore the ways in which the Orient was represented as pejorative throughout history and into the modern day. He argued that Orientalism was based on an ontological and epistemological division between the West and the Orient.

Said understood Orientalism to be predicated on the separation between the Self and the Other. This separation relies not only on the assignment of difference to the Other but also a desire for that difference. Representations of the Orient and Orientals were thus shown by Said to reflect European fantasies of the exoticized Other in addition to those representations that portrayed Orientals as unskilled, infantile, and bellicose. All these representations, however, remained inherently essentialist. Using stereotypical depictions, they culturally constructed the Orient as a homogeneous whole, neglecting all nuances present in reality. Because Said saw all writing, thought, and cultural production as political, all texts were political and laced with the prevailing cultural hegemony of the time period. Said’s own lifelong political commitment to the cause of the Palestinian people was intimately bound up with his critique of Orientalism.

One of the key ideas of Said’s analysis of Orientalism is imaginative geography. Imaginative geography refers to the reconceptualization of actual, physically bounded spaces with emotionally charged definitions that exceed and extend past the realities of those spaces. Through imaginative geographies, the distances between known and unknown spaces can be reduced while at the same time the exotic and mysterious elements of foreign places are intensified. Imaginative geographies reflect the fantasies and desires of those who create them and are inscribed within systems of power. Through these constructions, space not only becomes demarcated as “ours” and “theirs” but also involves the active appropriation of space, a process that was deeply instrumental to the expansion of the colonial state, as well as current imperial projects.

Historically, essentializing representations were produced on both sides of the East/West divide; however, the expansion of European colonialism and the overwhelming assumption of power by the West resulted in the prevalence of institutional Orientalism (as opposed to Occidentalism, or stereotypes of the Western world). Over time, Orientalism moved from being a largely academic subject to being instrumental in policy making and from an alien space to a colonial one. The conception of the Orient and Oriental peoples through biological and environmental determinism resulted in the “scientific” justification of the

Oriental as backward, incompetent, uncivilized, and in need of domination and enlightenment by the West. Additionally, Orientalism's masculine worldview helped develop the Orient as static and unproductive while at the same time sensual, exotic, and feminine.

As Orientalism evolved, the Orient became something that Europe needed for its own regeneration. Said contended that the West needed the Orient to define itself in contrast to the Other and that the West gained strength through this continuous (re)definition. The (mis)representations created by Orientalism are noteworthy not because of their accuracy but because they are part of a consistent and purposefully constructed discourse of alterity. Although Said's analysis was textual, he firmly believed that these textual representations had material consequences. Orientalism relies on the inscription of meaning on spaces and places, through poetic processes, which result in the development of a discourse of difference between "us" and "them." Textual production, he argued, produced more texts that could, in time, change reality and therefore create concrete consequences. Fictionality and reality thus help inform and determine one another.

For Said, Orientalism was not simply a historic construction of textual representations but a continuing phenomenon. He argued that Orientalism has not disappeared but has been reworked in a postcolonial world now controlled largely by the United States. In his work, he argued that modern American culture continues to depict the Arab Muslim in particular and essentialist ways that help perpetuate the United States' continued project of domination over the Arab world. Said specifically addressed the Gulf War of the early 1990s, and his later work concerned the aftermath of the events of September 11, 2001.

While Orientalism has been used and critiqued widely in other fields, it has also been employed extensively in geography. Said was particularly interested in space and place and discussed geography and spatiality throughout his writings. Geographical works on Orientalism are most notably found in the works of Derek Gregory. Said's work has been foundational to postcolonial studies, and investigations of knowledge/power and colonial and postcolonial states have used the critique of Orientalism as a point of departure. The critique

of Orientalism has also been employed to highlight the essentializing nature of some textual representations in geography's subfields, such as tourism and media studies. As Said noted, however, geography as a discipline was, and in some ways potentially remains, key to the processes of colonial and postcolonial domination by the West. The discipline of Orientalism, as well as Orientalism as a process, depended on the dissemination of knowledge about distant places and peoples by objective "experts." These "experts," geographers included, acted as gatekeepers and helped legitimize and enable colonialism. Geographers have more recently acknowledged how the discipline itself, much like the discipline of Orientalism, has been complicit in the construction and maintenance of disparate power dynamics between the colonial state and its colonies.

Critiques of Said's *Orientalism*

Said's *Orientalism* was critiqued for a number of reasons. First, it was argued that Said's humanism, which is based in a Western Enlightenment tradition of humanism, could not be reconciled with Foucault's antihumanism. Said's assignment of agency to the individual author runs counter to the idea that informs it, that is, Foucault's concept of the capillaries of power. As such, it was argued that Said's methodology was inherently flawed and that he quit using his Foucauldian methodology when it interfered with his humanism.

Additionally, Said's critique of Orientalism was criticized for being simplistic. Some critics argued that in exploring the division of the world between the West and the Orient, Said not only documented but also reinforced binaries that were inattentive to more nuanced representations of peoples and places. In this vein, the critique of Orientalism did not provide space from which to break out of this dichotomous worldview. Said himself called for an alternative to Orientalism but did not elaborate on what this might look like. It has also been argued that Said gives insufficient thought to the interchanges of power and the ways in which the seemingly totalizing power held by the colonizer might be contested by the colonized, especially in localized, daily practice.

Said was also criticized for his explicit focus on British and French Orientalisms and his neglect of

other Orientalisms (e.g., German and American). He argued that this was justified because the British and French had been the most influential in the production of Orientalist discourses as well as in colonial expansion. Said's political commitment to Palestine and his interest in Egypt were undoubtedly other key components of his choice of focus on British and French Orientalisms. Other critics contended that Said neglected analysis of texts that disagreed with his thesis of the overwhelmingly dominant discourse of Orientalism. His use of texts from various time periods also led to a critique that the work was transhistorical and therefore ahistorical. His work was viewed by some as elitist in its examination of solely "high culture" and the academic discipline of Orientalism. Said never relinquished his affinity with the Western literary canon that he himself critiqued, and this also remained a point of contention among his critics.

Last, feminist scholars have noted his inattention to the place of gender within the discourse of Orientalism. While Said does discuss the feminization of the Orient, his attention to gender remained primarily in the metaphorical association of the Orient to femininity. Scholars have sought to deepen and further problematize the dichotomy between the West and the Orient, as well as to investigate the material practices and experiences of gender within Orientalism. Although it is noted that Said did open up space for the expanded exploration of gender and sexuality, it has been argued that these subjects are much more important than he made room for in his analysis. Feminist scholars have also questioned whether Said's regional and, at times, global scale of analysis undermines critiques of local institutions and politics.

Orientalism's Use Within Geographic Subfields

Said's focus on Orientalism as a phenomenon experienced only by the Middle East has more recently been extended to the former colonies, including Africa, Eastern Asia, and Australia. While much work on Orientalism has been historical in nature, geographers and other scholars continue to critically engage with the theory in a modern context. Within geography, the critique

of Orientalism has been used in a number of ways. Said's interest in literature and art has been extended by geographers concerned with other textual production such as travel writing and tourism. Within postcolonial and development geographies, the critique of Orientalism has been used to explore the ways in which essentialist representations help perpetuate relationships of dependency even within a postcolonial context.

ORTELIUS (1527–1598)

Abraham Ortel (although always referred to using the Latin form, Ortelius) was born in Antwerp. He was a prominent citizen of that great trading city, and he conducted his scholarly and publishing activities from there until his death. He was one of many scholars involved in drawing and publishing maps in what was then the Spanish Netherlands (he became cosmographer to King Philip II of Spain), but his distinctive contribution

Figure 1 World map from the Theatrum Orbis Terrarum

Source: Library of Congress.

was that he was the first to produce an atlas of the world, titled *Theatrum Orbis Terrarum*, in 1570 (see Figure 1).

While there had been many collections of maps made before Ortelius, they were either updates of Ptolemy or random collections of maps copied from diverse sources and simply bound together. Ortelius's innovation lay in his overall plan for what he did: He wanted a uniform set of maps to cover the whole world as *then* (i.e., in his own time) known to Europeans. This set of maps would be compiled from all the available sources and not simply copied from whatever map was available for a particular region. This interest in having a set of maps based on the best available sources was openly indicated in the atlas in that his sources for each map are stated; and this collection of information brought Ortelius into communication with most of the geographers of his time. He also consciously set about distinguishing his contemporary maps from those that he drew to show classical civilization or the biblical lands. In making this distinction, he was the first to create a historical atlas; and eventually, he removed these historical maps into a separate atlas, the *Parergon*, in 1579, which was included in later editions of the *Theatrum*. In the *Theatrum* proper, Ortelius employed a thoroughly empirical approach to mapping; while in the *Parergon*, he adopted a different hermeneutical principle—"geography is the eye of history"—and his aim was to produce maps that would bring clarity to the study of the past and its classic, often indeed sacred, texts.

He was in close touch with another famous atlas maker of the period, Gerardus Mercator, and may have inspired aspects of the latter's work. The *Theatrum*, published originally in Latin, appeared in Dutch, German, French, Italian, English, and Spanish editions (several in the case of each of these languages) until 1624. It remained as an influence in the work of subsequent generations such as Hondius, Janssonius, and Blaeu; many of the conventions he established in the *Theatrum* remain in atlases to this day.

OTHER/OTHERNESS

The classification of Other and the demarcation of Otherness refer to an identification of difference based on race, ethnicity, sex/gender, often under the guise of the exotic and the strange. This Otherness can also be understood (and experienced) as forms of marginalization and exclusion. However, Othering differs from other forms of oppression as it explicitly calls attention to the power dynamics between the person/institution, defining the "Otherness" and the person/place experiences the classification of "Other." In this entry, Edward Said's writings on Orientalism are used as a starting point for understanding how geographers working on issues of identity, urban space, power dynamics, postcolonialism and feminism approach, study, and critique the process of Othering.

Geography is drenched in imperial representations and colonial mappings of the Other. Explorations into seemingly unknown territories and populations, whether rural or urban, expose entrenched Western perspectives of geographic research. Over the past 30 years, human geography, specifically postcolonial and feminist perspectives, has critically examined the process, the placement, and the resistance generated from the position of the Other. Geographical mapping is drenched in imperial representations and colonial mappings of the Other.

The process of Othering and the demarcation of the Other are conceptually distinct yet theoretically intertwined. The process of Othering can be illustrated through Edward Said's critique of Orientalism. For Said (1979), Orientalism (generally understood as the study of "the Orient") was a "way of coming to terms with the Orient that is based on the Orient's special place in European Western Experience" (p. 1). Orientalism allowed a Western European perspective to control the image of "the Orient." It was a way to dominate, restructure, and exert authority over the Orient through the study and classification of people and places. The Orient, according to Said, was and is not a "free subject of thought or action" (p. 3). The Orient became a static object of study through the process of Othering.

Othering produced overtly generalized perceptions of particular groups of people based on behaviors associated with a stereotypical notion of place. Othering relied and relies on relational representations of the Other. The process of Othering exposes as much about the Western process of inquiry as about the object of study. Through Othering, the European culture shaped its identity and buffed what it perceived to be its strengths in relation to that which it perceived to be inadequate in "the exotic." Othering relies on subtle methodologies of power and control.

Postcolonial studies expose how certain bodies, in relation to the hegemonic notion of whiteness, are not endowed with agency and are perpetually linked to a discursive representation of place. Debates on race and culture are not the sole conceptual framework for understanding Othering. Postcolonial studies and feminist literature influenced by Simone de Beauvoir have also described the experience and placement of the disempowered Other through the constructs of colonialism, racism, and patriarchy.

In human geography, the Other is understood through discussions of space and identity. The organization of space creates spaces of marginalization and exclusion, the space of the Other. For example, legislation banning panhandling distinguishes appropriate commercial uses of the space of the sidewalk. Classifying a neighborhood as "Chinatown" creates imagery of ownership, belonging, segregation, and racialization. Geographers have examined the process of Othering

through situating the Outsider residing on the periphery of cities, countries, and social thought.

Today, most human geographers do not describe—in an Orientalist manner—detailed characteristics of the space of the Other. They critically examine and question how this demarcation of Other space and associated identities is categorized and maintained. Geographers question the process of Othering through critiquing the territorialization of space and exposing inequalities based on identity. These critiques do not explicitly use the language of the Other; instead, Othering is understood through depictions of enclosure, exclusion, and difference.

Urban geographers researching economic and legal inequalities and public claims to urban space explore Othering in the city. In addition, research conducted on national sovereignty, border anxiety, sanctuary cities, and migrant workers analyzes Othering through destabilizing the notion of territories and boundaries. Here, the concept of the Other helps destabilize concepts of territory and borders. Othering does not rely on stabilizing but forces mobility on those deemed as Other. Feminist critical race scholars and queer theorists in geography incorporate Othering into their research—from bounded spaces to a critique of heteronormative spaces, to the segregation of gendered work, to racialized identities based on place.

To fully understand the concept of Othering, one must be aware that the space occupied by those depicted as Other are not one-dimensional and neutral spaces on the periphery of society. The space of the other, the space of exclusion can be centrally visible. Similarly, the space of the Other can also be a space of resistance. A neat line between oppressor and other is not always present. Othering is also prevalent in communities that would self-classify as the Other, feminism and geography being no exception. Othering can reflect Western society at large, our discipline and personal research projects. Othering is not simply about identifying the Other as a static racialized identity. It is a process of reflection on how dominant powers represent Others.

Geographical work on outsourcing originated in the 1980s, when the Fordist system of mass production entered a worldwide crisis. The geographers Allen Scott and Michael Storper, working on industrial change in California, described the emergence of tightly interconnected networks of small firms in place of the previously integrated large businesses. Without using the term *outsourcing* directly, they described a regional pattern of firms adopting outsourcing to spread risk and contain costs. These early works introduced a spatial component in the analysis of outsourcing: The concentration of providers of outsourcing services in certain regions allowed for an easier and more efficient coordination of the production processes.

Later, the Washington Consensus of neoliberalism and the worldwide increase in international trade led geographers to shift focus from domestic to international outsourcing. Overall, they identified the distinctive character of the current phase of economic globalization as international fragmentation of production, involving a production process spread across production sites in various countries. Outsourcing and intrafirm trade within large corporations are the mechanisms allowing such fragmentation. International outsourcing is a qualitatively new phenomenon, because the earlier phases of globalization involved mostly trade of finished products.

In recent years, geographers have analyzed the economic and sociocultural consequences of outsourcing while participating in interdisciplinary schools of thought, such as (a) the Global Value Chains (GVC) Initiative, (b) the work on Global Production Networks (GPN), and (c) within the discipline, the work of economic geographers analyzing global as well as regional change.

The value chain describes the full range of activities that firms and workers perform to bring a product from its conception to its end use and beyond. The GVC Initiative investigates the global expansion of value chains through international outsourcing and direct investments, and its consequences on innovations, local firms, and labor. The work on GPN expands the analysis of value chains, arguing that “the notion of a simple single-stranded ‘commodity chain’ scarcely does justice to the complexity of the processes involved” (Jackson,

OUTSOURCING

Outsourcing refers to subcontracting a production process, or the provision of a service, to a third-party company. As a result of outsourcing, firms transfer entire business functions to external service providers. Geographers have contributed to the study of outsourcing by investigating (a) the spatial aspects of outsourcing, (b) the social and cultural effects of the trade flows generated by outsourcing, and (c) the role of outsourcing in the globalization of the economy.

Figure 1 International outsourcing between Western Europe and Bulgaria. Firms in high-wage countries (in the table, the EU 15—the 15 Western European members of the European Union) export cloth to low- and medium-wage countries (Bulgaria). They outsource the sewing and stitching to producers in the low-wage countries and reimport the finished apparel products.

Note: The data refer to knitted cloth and apparel. The values are expressed in euros.

2002, p. 6). Instead, it represents the relation among firms as complex, network-like, and regulated by a variety of institutions at different scales. One example of regional analysis is the work by John Pickles, Adrian Smith, Robert Begg, Milan Bucek, and Poli Roukova on Eastern European apparel industries. They analyzed the role of international outsourcing in revitalizing the

industry (Figure 1), its consequence on labor conditions and wages, as well as the impact of norms and regulations on the industry.

P

PALIMPSEST

A palimpsest is a conceptual model of a place as a multilayered structure that emphasizes the coexistence of multiple visions and impacts of different cultures on the landscape. Originally the term referred to a type of medieval manuscript in which new text was written over previous text that had been partly erased, palimpsest has become a widespread metaphor for cultural landscapes coincidentally with the rise of interest in the symbolic properties of landscape, semiotics, and representation.

Origins of the Term

The term *palimpsest* originates from the Greek *palin* (“again”) and *psaio* (“I scrape”). The notion became a useful metaphor in the humanities and in fiction more than a century ago. It was used by scholars in humanities disciplines to depict the layering of different texts on one piece of parchment, in which subsequent layers do not erase all the traces of their predecessors. It was stressed that the earlier layers of the palimpsest did not disappear and remained visible through the more recent layers, so that one can recognize the previous layers of the text. This approach was used in architecture and urban history to describe the coexistence of material elements that originated in different historical periods in a building or urban site.

This vision was close to early-20th-century research on cultural landscape, since Carl Sauer emphasized the role of temporal change of the landscape. This notion was followed by Derwent Whittlesey’s writings on sequent occupance in the 1920s. Time passed before the vision of a landscape as multilayered came into usage in geography. The first geographer to call a landscape a palimpsest was Donald Meinig, who used the term in 1979 in the preface to his edited book *The Interpretation of Ordinary Landscapes*. What Meinig meant was that the making of the landscape is a temporal process and the landscape itself reflects some of its past properties. The historical model of landscape as a palimpsest includes the genesis of its various elements—an approach that shows that some of them remain in place for long periods of time, some have changed, some have been forgotten, others have been reinvented, and, finally, some have been totally destroyed and new elements have emerged in their place.

Symbolic Landscape as a Palimpsest

As the symbolic properties of the cultural landscape were stressed in the “new cultural geography” and emphasis was put on human interpretations and representations of a landscape, the metaphor of place as a palimpsest became popular. The emphasis in this approach was on differences in the landscape as it is “read” by social groups and individuals, differentiated

by identity, occupation, lifestyles, experience, imaginative power, and emotional factors. A palimpsest indicates that the landscape consists of different fragments of the text, which can conflict with one another. This interpretation of the term turns reading of the landscape into a process of multivocal communication and the text into an “intertext.” The *intertext*, in semiotics, is a structure of mutual references of multiple meanings; the same is true of the palimpsest in geography.

Semiotic Model of a Palimpsest

To study the relations between various layers of place as a palimpsest, the semiotic model is needed if the landscape itself is to be regarded as a text. The concept of mythogeography, which appeared in Russia in the early 2000s, suggests such a model; here, place is seen as a complex of an endless number of coexisting semiological systems. Each of these systems is one of the layers of the palimpsest, and each layer is regarded as a context, not a narrative, because it is organized around one dominant idea. Such contexts may be the geographical description of a place, place perceptions and imaginations, images and metaphors of a place, and so on. Semiotics helps analyze these layers as spatial myths, and the process of their formation is one of semiosis. The essence of this approach is in the endless interpretation of place, during which the new senses of a place emerge.

Criticisms of the Model

The model of place as a palimpsest originated in historical and cultural geography and can be described as one of several ways to describe cultural changes in a landscape. The theory of spatial diffusion is a “dynamic” alternative to the palimpsest, as the vision of a place as a sum of elements with different times of origin. Another criticism is that palimpsests represent landscapes as passive entities, only as reflections of human interpretations and perceptions. The semiological model is useful to stress the role of the landscape itself in the formation of new layers of the palimpsest.

The model of place as a palimpsest may be used in tourist destination management, marketing of territories, regional promotion, and other

activities in which the construction of new images of space and place is needed.

PANCHROMATIC IMAGERY

Analog and digital sensors that acquire data from a single broad region of visible light, and sometimes from the adjacent near-infrared and ultraviolet regions of the electromagnetic spectrum, are commonly given the label *panchromatic*. The name was originally given to black-and-white photographic films that were sensitive to ultraviolet and the entire visible spectrum (*pan*, meaning “all,” and *chromatic*, meaning “colors”; both words are of Greek origin), to distinguish them from earlier black-and-white films that were only sensitive to ultraviolet and blue light. Panchromatic film was used extensively for aerial photography. In the era of digital electronic sensors, the term *panchromatic* has been retained for single-band images that represent information from a broad spectral region but not necessarily from all visible wavelengths. Panchromatic satellite images typically have relatively high spatial resolution compared with multispectral images and are useful for cartographic

Figure 1 Example of panchromatic film sensitivity and IKONOS relative responsivity. The yellow region indicates approximate wavelengths of human vision.

Source: Author.

applications and visual interpretations of land cover. Panchromatic images are sometimes also used to “sharpen” lower-spatial resolution multi-spectral images, in a procedure known as multi-resolution data fusion.

Panchromatic Film

Photography is an analog, chemical method of recording images. Silver halide crystals suspended in gelatin form an emulsion and undergo a chemical reaction on exposure to ultraviolet, violet, and blue light, thus recording the spatial patterns of light that fall on the film. However, because of the limited spectral range of the silver halide crystals, black-and-white photographs produced from this film did not provide an intuitive correspondence to human visual perception. In 1873, Hermann Carl Vogel discovered that by adding small amounts of sensitizing dye, the silver halide

crystal sensitivity to light could be extended to include green wavelengths, a type of film known as orthochromatic. Finally, in 1904, Vogel developed a dye that extended the silver halide sensitivity range to include red. The resulting black-and-white photographs were more visually intuitive than those from the earlier films, and the name panchromatic was chosen for the new film. In 1919, infrared films were developed by extending the sensitivity range even further. In contrast to all black-and-white films, including panchromatic film, color films have three emulsion layers, one for each of the red, green, and blue portions of the spectrum.

Panchromatic film is prized for its broad spectral response, from approximately 0.25 to 0.7 micrometer, and was the traditional film used in aerial photography (Figure 1). Because the atmosphere preferentially scatters shorter-wavelength light, and thus especially ultraviolet and blue light, panchromatic aerial film was

normally exposed with a yellow filter to remove the blue and the shorter wavelengths. Thus, despite the name, panchromatic aerial photography typically does not record all visible wavelengths.

A wide range of aerial panchromatic film types were produced in the past, with varying contrast, light sensitivity, and spatial resolution. In recent years, with the increased use of digital aerial sensors, many types of panchromatic aerial film have been discontinued.

Satellite-Based Sensors

During the early part of the space era, traditional photographic film was the primary medium for acquiring images of Earth, both by astronauts and by automated satellite-based sensors. Consequently, aerial film terminology was used in space-based imaging from the beginning, including for Corona, a U.S. intelligence program that was the first satellite-based Earth-imaging program. The Corona program lasted from 1960 to 1972, and the majority of Corona imagery was acquired with the equivalent of panchromatic film.

In 1972, the National Aeronautics and Space Administration (NASA) launched a terrestrial-imaging satellite, the Earth Resources Technology Satellite, which was later renamed Landsat. The Landsat program has been remarkably successful and continues to this day. A less well-known sensor on the Landsat satellite was the Return Beam Vidicon (RBV). For Landsat 1 and 2, the RBV sensor collected data in three spectral bands, but for Landsat 3, launched in 1978, the RBV sensor was redesigned to acquire just a single broad band (Table 1). Following the tradition of excluding blue wavelengths when acquiring aerial images with panchromatic film, the RBV sensor was designed not to be sensitive to blue wavelengths. Although data from the Landsat sensors were electronic signals converted to a digital format, the film term *panchromatic* was applied to the single-band RBV data.

The first satellite program designed explicitly to have an integrated combination of multispectral and panchromatic sensors was *Système Pour l'Observation de la Terre*, or SPOT. Designed by the French Centre National d'Etudes Spatiales (CNES), the SPOT-1 satellite carried a High Resolution Visible (HRV) instrument, which collected

panchromatic data with a 10-m (meter) resolution and three-band multispectral data with a 20-m resolution. SPOT 1 was launched in 1986. All subsequent SPOT satellites, up to the current SPOT 5, feature this combination of multispectral and panchromatic data, although the particular wavelengths of the panchromatic band have changed progressively between the different satellites (Table 1). For example, the SPOT-4 panchromatic band is only sensitive to red wavelengths.

A wide range of digital space-borne sensors have followed the SPOT design, with a combination of high-spatial resolution panchromatic and low-spatial resolution multispectral data. Examples include the India Remote Sensing (IRS-1C) satellite's Linear Imaging Self-Scanning sensors (LISS-III), with a 5.8-m resolution panchromatic spectral band and four bands of 23.5-m multispectral data, and Landsat 7's Enhanced Thematic Mapper Plus, with six multispectral bands with 30-m resolution, one thermal band with 60-m resolution, and a panchromatic band with 15-m resolution. The two high-spatial resolution commercial sensors, IKONOS and QuickBird, also have a combination of a high-spatial resolution panchromatic band and four lower-spatial resolution multispectral bands. Figure 1 shows that the spectral responsivity of the IKONOS panchromatic band is dominated by red and infrared, in contrast to the sensitivity of traditional panchromatic film, which includes the ultraviolet and the visible.

The combination of panchromatic and multispectral data is attractive because satellite-borne sensors are normally constrained in terms of the total information that can be acquired and communicated. Therefore, there is a trade-off between the spatial resolution (the amount of ground detail) and the spectral resolution (the number and width of the spectral bands) that can be collected by any one sensor. By acquiring a data set at high spatial resolution with just one band (low spectral resolution) and also acquiring a second data set with comparatively low spatial resolution and three or more spectral bands (of higher spectral resolution), the best of both worlds may be obtained.

Applications of Panchromatic Imagery

Panchromatic aerial photography was traditionally used for photogrammetry, especially in the

production of topographic maps. In addition, panchromatic aerial photography was used extensively for qualitative image interpretation.

Map production is also a primary application of panchromatic imagery acquired from satellites. Although panchromatic data alone are relatively rarely used in automated remote sensing land cover mapping, due to the lack of multispectral information, panchromatic data are useful for a number of spatial image analysis methods, including both automated and semiautomated road delineation. An additional use of panchromatic imagery is in multiresolution data fusion, which has become a research focus of considerable interest. Multiresolution data fusion encompasses methods that integrate the spatial detail from high-spatial resolution panchromatic data with the spectral

information from lower-spatial resolution multispectral data.

PANOPTICON

The panopticon was a prison model developed by the English social theorist and philosopher Jeremy Bentham in the late 1780s and has, subsequently, been implemented in prison design and construction around the world. The panopticon's design was such that everything (*pan*) could be seen and observed (*opticon*) at any time. Panopticism as a social theory emerged in the 1970s as a way of theorizing relationships between power, surveillance, and society. Highly influenced by Michel Foucault's famous book *Discipline and Punish*, panopticism contends that surveillance and power are intimately intertwined and manifest through particular procedures and apparatuses connected to technological inventions. Panopticism holds that these procedures, apparatuses, and technologies ultimately serve to discipline society, eliminating obfuscation through observation.

Bentham's Panopticon

Bentham is most famous for the development of the panopticon prison model, though much of his life work revolved around social reform and the advent of utilitarianism. The basic design model of the panopticon prescribed a tower in the center of the structure from which all surrounding inmate cells could be observed and noted; this tower was also kept darker than the rest of the structure. Bentham noted that this design not only enabled constant surveillance but also made inmates *feel* as if they were constantly observed, thus turning individuals into objects of surveillance instead of participants in communication. The circular aligned cells around the central observance tower allowed the warden to be omnipresent, or at least *seem* to be so. This feeling of being under constant surveillance on the part of the inmates and the sense of the warden's omnipresence exemplify the ways in which power seeped into the everyday lives of prisoners. It is this very concern on which Foucault focused.

Foucault's Panopticon

Foucault's interest in panopticism stemmed from his reading of Bentham's prison model, which he

then applied to other social institutions, such as the state, education, religion, and technology. Foucault contended that Bentham's panopticon design brought to light ideas about order and power that have long existed. In the panopticon, Foucault observed that the orbital design, which enabled inmates to be viewed at all times, meant that those people doing the viewing amass a great deal of power. In this scenario, a few people retain power, while numerous people are affected by the manifestation of such power. This same consolidation of power in which multitudes are affected by a few powerful actors, maintained Foucault, can be witnessed in myriad social institutions. Some scholars of Foucault contend that his observation of the ordering and disciplining of society emerged from a basic skepticism about modernist projects and ways of thinking.

Critical Panopticism

Foucault's panopticon reading has been influential in broader human geography discourse, especially in the critical traditions of feminism, Marxism, and poststructuralism. In feminism, heterosexuality is conceived of as a panopticon, or something due to which people discipline themselves regardless of whether their actions or lives are directly being monitored. Many women and gays fear the discriminatory heterosexual gaze, and thus, the metaphor of the closet, in which many gay people are trapped, comes into play. Marxism has been much concerned with the role of state power and surveillance in controlling classes and in consolidating power among the elites, and different trajectories of Marxist thought have expanded panopticism in numerous directions. Poststructuralists use panopticism to understand the relationships between and within subjectivity, normativity, and power, both discursively and materially. These varying critical schools of thought share the concern of how these powers and procedures are spatialized, how they affect people's interactions with and in space, and how these geographies are normalized and become part of the fabric of everyday life through careful study of the discursive and material histories of panopticon organizations.

Geospatial Technologies and Panopticons

The simultaneous increase in surveillance technology and in geographic spatial science technologies has led to new questions in surveillance studies. Scholars increasingly consider the ethical and moral dimensions of publicly available surveillance and mapping technologies. Also, the effort to spatialize the myriad types of information—that is, to be able to show information via maps and visual, spatial representations—leads to questions of for what this information will be used and whether or not people can opt out of participation from these spatial technologies. Others argue that surveillance technologies result in a lack of cohesion in neighborhoods and cities; there is no longer a need to be aware of neighbors and surrounding people, since surveillance technology is there to capture any wrongdoings. The panopticon, then, leads to order and discipline—that is, by interrupting interpersonal relationships through surveillance.

PARKS AND RESERVES

A *park* or *reserve* is an area that has been legally set aside for protection. The form of protection ranges from minor limitations on the use of certain materials or products to the complete exclusion of

people and communities, some of whom may have been moved from within the area designated as a park on its creation and continue to be excluded from its boundaries, to ensure complete protection of the land and resources within the park. This is a key area within the field of geography, as it involves land or ocean resources and the people who live on or use them and, as such, is a key area of people-environment interaction within the larger field of conservation. There are many forms of protection, for land, water, or biodiversity, in existence around the world today. According to the International Union for Conservation of Nature (IUCN), protected areas are land or ocean regions dedicated specifically to the protection and maintenance of biological diversity and to their associated natural and cultural resources, which are managed in some type of legal arrangement. There are many different forms of protection, however, which can be confusing, and so IUCN has also defined these various types, in terms of their level of protection, objectives, and interventions. These different types are (a) *strict nature reserve*, which is managed mainly for science; (b) *wilderness area*, which is managed mainly for wilderness area; (c) *national park*, which is managed mainly for ecosystem protection and recreation; (d) *natural monument*, which is mainly for the conservation of specific natural features; (e) *habitat/species management area*, which is managed mainly for conservation through management intervention with the purpose of ensuring the maintenance of habitats and/or to meet the requirements of specific species; (f) *protected landscape/seascape*, which is managed mainly for landscape/seascape conservation and recreation; and (g) *managed resource protected area*, which is managed mainly for the sustainable use of natural ecosystems, such as the U.S. Forest Service lands.

Global Coverage and Location of Parks

According to estimates based on these IUCN definitions of parks and reserves, there are more than 117,000 such sites, covering approximately 19 million km² (square kilometers), or approximately 4% of the Earth's surface. This is an increase in legal designations of such sites from only 9,214 in 1962, covering an area of 2.4 million km². Overall, there are approximately 20 million km² of

Earth's surface in some form of protection (some of which may not have much monitoring or effective management and so are referred to as "paper parks," reflecting the fact that while these areas appear as parks on maps or paper, they are not actively protected or managed), which represents about 15% of Earth's surface. The oceans, in contrast, have only 1 million km² in any form of protection, which represents around 0.5% of their total surface area.

Many of the world's largest parks occur in areas where the land is perhaps less suitable for other options—that is, land that is not settled or inhabited for a good reason. Such land has less worth economically speaking and was not developed, and so now it enters a park system. An example of this is the Greenland Natural Reserve, which encompasses a large area of ocean and ice caps, or the Ar Rub'al Khali Wildlife Management Area in Saudi Arabia, which encompasses a large part of the world's largest unbroken desert. In some areas, though, and increasingly with current park creation, parks are located within inhabited landscapes and on land that is more valued. In such cases, additional problems and potential conflicts can arise. Such park landscapes are often characterized by biological and sociopolitical dilemmas because of conflicts between biodiversity goals and local livelihood strategies. Throughout the developing world, parks are surrounded by landscapes that, while still containing considerable biodiversity, also have rapidly growing human populations. While areas around parks represent zones of risk and restriction, they are also potential zones of opportunity for current and potential migrant populations. This dual character of park landscapes will generate and/or intensify the distinctive patterns of land use around parks, which will in turn have important consequences for the park itself. Such conflicts will likely increase as human populations and competition for existing natural resources increase.

Development of Connected Parks or Corridors

These areas of protection are being set aside for the conservation of land, ecology, or biomes or, in some cases, to preserve a very particular

species. A major concern for conservationists, however, has been the "islandization" of parks. Increasing human populations and the expansion of agriculture are viewed as major contributing factors to this problem, whereby the park becomes an island of, for example, forest, within a larger-landscape matrix of human-dominated uses, such as various types of agriculture and settlements. Kibale National Park in Uganda is a prime example of such a situation, where the park represents a forested island within an agricultural, densely populated landscape. This park highlights many of the concerns of islandized parks, as it contains significant chimpanzee, monkey (e.g., various Colobus monkeys), and forest elephant populations within a small space on the landscape (less than 350 km²). In addition, then, to the series of parks being established worldwide, there are also other areas or reserves being established in concert, which allow connections or corridors from one park to another, as many people have begun to realize that purely islandized parks may not be the most robust solution for long-term conservation, especially for species with larger home ranges, which need to maintain diverse, healthy, and robust populations. The development of such linkages or "corridors" is still under way in many world regions as areas are created to link existing parks on the landscape to each other, often with less rigorous rules of protection but still categorized as protected in some form. In the Kibale National Park, a corridor is being developed to link this small, forested park to the larger Queen Victoria National Park to its south, although these regions differ in terms of ecosystems and species composition. Such corridor regions are expanding globally and adding to the annual increase in total land area under protection, although their success is not yet known.

Effectiveness of Parks and Reserves

There are a multitude of park and reserve forms in existence around the globe, usually with the goal of species, biome, or society conservation. Depending on the form, rules, and size of these parks, the successfulness of the venture may vary. Some parks are purely paper parks, in that while they may exist on paper in some central office

Grand Teton National Park, Wyoming

Source: Morguefile.

somewhere, there is no actual impact on the ground due to the park being there, and local communities and peoples rarely know of the park boundaries, no guards are present, and no monitoring is undertaken. At the opposite extreme is “fortress conservation,” in which there is complete exclusion of people from the park environment and the park is a restricted zone for society. Such parks can have some significant problems if a population has been excluded from it and if there are no alternative sources of goods for that population. Such parks are common throughout Africa and Asia. Due to the many different forms, rules of use, and purposes of park establishment, it is difficult to characterize the general success of park and reserve establishments.

Recent comparative studies that have attempted to evaluate the effectiveness of parks in tropical regions suggest that the creation of protected areas has had mixed outcomes. While exclusionary approaches can be successful, in some instances, at protecting forest cover, they do not account for the social ramifications of denying local inhabitants access to forest resources. Even as the area under protection continues to increase worldwide, there is an ever-greater awareness of the social consequences of creating protected areas that exclude local inhabitants from traditional ways of life. People-park conflicts are particularly acute in tropical regions, where people depend on high-biodiversity regions for their livelihood. The interest in alternative, decentralized

methods of forest management in several countries across the world can be traced to these concerns. Sustainable levels of use have been proposed as a more effective alternative, based on the argument that resources are better conserved when people can use, and therefore value, them as part of their livelihood. Thus, the trend has shifted toward encouraging decentralized, local, and participatory forms of governance in contrast to the top-down, state-centered systems of management that were extensively promoted in the 1950s. However, critics of these approaches argue that exclusionary approaches are the most effective way to conserve habitats and protect biodiversity.

A recent study by Bruner et al. evaluated the effectiveness of 93 parks in tropical regions. All the sample parks were exclusionary in their management. The study made an important contribution by attempting a broad, comparative analysis, and it concluded that exclusionary parks are successful at limiting land cover transformation when compared with the surrounding landscape. However, by focusing only on exclusionary forms of management, the research fails to consider whether alternative approaches, such as community-based arrangements, private ownership, or participatory park management, might have similar or better results. In the future, there will probably be a continued increase in park development, and many new parks may form part of a more community-based arrangement. The increasing importance of the role of private ownership within the parks and conservation arena is also expected. More studies to evaluate park and reserve effectiveness are still needed, as is the larger discourse on the type of conservation and the role it plays in the ultimate success or failure to conserve. Such studies are being undertaken and will only increase as the emphasis on the conservation of such parks and reserves continues to increase.

PARSONS, JAMES (1915–1997)

James Jerome “Jim” Parsons was a noted cultural geographer in the tradition of Carl Sauer. He was a professor in the geography department at the University of California, Berkeley, from 1948 to 1986. He was an advisee and student of Carl Sauer, long recognized as one of the most influential modern geographers. Parsons obtained his PhD in 1948 at Berkeley and was hired to stay there. As a student of Sauer’s, and because he never left Berkeley, Parsons is often so directly linked to Sauer as to not be seen as different from his mentor.

A review of his academic work and publication record suggests that Parsons was a generalist and that the topics he researched and studied were closely aligned with the Berkeley School of geography. While advisees who completed their PhD degrees early in Parsons’s career said that their mentor’s philosophy was so closely tied to Sauer that little distinction could be made between the two, Parsons’s later students viewed him as decisively different from Sauer.

Parsons's publications show an intense interest in the "man-land" tradition of the Berkeley School, but they also indicate a substantial divergence into biogeography, especially his work on the interface between human and mammal communities and on human use of and impacts on vegetation. Examples of the former are his research on Spanish starlings and Caribbean green sea turtles. In the case of sea turtles, his 1962 book *The Green Turtle and Man* is seen as one of his most important contributions, coming at a time before the widespread international concern over species overexploitation. Parsons's work on turtles dovetails pioneering studies by the famed marine biologist Archie Carr. In that respect (and others), later students of Parsons view him as the originator of biogeography in the context of human-environment interaction, or what has been termed *cultural biogeography*.

Parsons shared Sauer's philosophy of deeply rooted and dedicated field observation. Unlike Sauer, however, Parsons turned farther from archival work and historical geography to contemporary topics that relied as much on local knowledge and practices. As president of the Association of American Geographers in 1976, Parson gave an address to the professional association that focused on his vision of geographical inquiry as "exploration and discovery." This call reflects his openness to seeking out topics in the field, learning from unorthodox sources, following up with archival research, and communicating in unobtrusive language.

PARTICIPANT OBSERVATION

Participant observation is a research methodology with roots in anthropology. It has a well-established tradition in exploratory social science and geography. In practice, participant observation shares several characteristics with ethnography. One of the aims of participant observation is to uncover the everyday life of different groups within society. It is generally agreed that participant observation is a broad observational approach that is not used in isolation from other methods, such as more quantitative techniques. Participant observation has been used by geographers to explore a wide variety of populations and settings.

The methodology originated in the fieldwork of social anthropologists such as Bronislaw Malinowski, but participant observation's heritage in geography is perhaps best linked to the Chicago School of sociology during the 1920s and 1930s. Nels Anderson's classic work *The Hobo* pioneered participant observation as a research methodology in urban sociology. Anderson attempted to provide insight into and an understanding of the life of the homeless in Chicago. This tradition of seeking insight and understanding continues to this day in geography. The methodology has proved to be particularly suited to exploratory research because participant observation overcomes the potential weakness of relying on a single methodology, which may prove to be ineffective in uncovering everyday experience.

Participant observation aims to uncover the meanings and perspectives of persons living in particular places. Early definitions of the methodology talk about sharing in the daily activities, and sometimes the interests, of a group of persons. This definition has changed little over the decades. Participant observation often takes place in a case study location that has some relevance to the research question. This methodology is unique because the researcher approaches participants directly within their own environment rather than having the participants come to the researcher via, for example, a questionnaire survey. The participant observation researcher strives to uncover what everyday life is like from an "insider" perspective while remaining, inevitably, an "outsider."

Participant observation has been claimed to represent a uniquely humanistic, interpretive methodology, as opposed to the positivist tradition. The methodology usually shares the following characteristics. First, there is an emphasis on exploring the nature of a social phenomenon rather than testing a hypothesis. Second, participant observation research usually takes place over an extended period of time, often several months to years. Third, the methodology uses a wide range of unstructured data, such as verbatim quotes from participants and key informants. Fourth, the exploration usually focuses on a small number of persons and is often in the format of a case study. Last, analysis of the data involves interpretation of the meanings of human behavior and actions. The written product is often descriptive, with a rich use of quotes and photographs. Traditionally, quantitative data were either nonexistent or played a limited role. Today, this is changing, with a greater focus on the use of mixed methodologies that do not exclude the use of qualitative or quantitative data. Participant observation is increasingly experiencing something of a renaissance within social science, although it also continues to be subject to critical scrutiny and revision. Most qualitative researchers using participant observation methodology agree that the key to validity is clarity. This clarity can be framed within a set of previously established criteria to test the reliability of a particular exploration.

Perhaps one of the best examples of the use of participant observation in geography is David Ley's monograph on the black inner city as a frontier outpost. Using a wide range of techniques, he explored the variety of images of a black inner-city neighborhood in Philadelphia. His techniques included an intensive 6-mo. (month) period and a more extensive 30-mo. period of participant observation, supplemented by data gathered from documentary sources and various forms of interviewing. Ley viewed the neighborhood as a frontier outpost, having an external environment of hostility and uncertainty and an internal environment that focused on connectivity and cultural separation as a means to meet the challenges imposed by the external environment.

Graham Rowles, in his study of older people's experience of space, went beyond participant

observation to become directly involved in their lives. Rather than remaining an outside observer, he became part of the experience. His research involved sharing conversations with older persons in their homes, at community meetings, and in everyday life experiences. The result was a collection of five vignettes describing the geographical experience of the elderly blended with a theoretical framework on their experiences. Rowles's intention was to foster greater understanding of how the elderly cope with changes in their environment.

More recently, participant observation has been used in geography to answer a wide range of questions concerning the meaning of space and social conflict. Feminist geographers, in particular, have found the methodology useful in exploring and rewriting geography to include the female perspective. Participant observation will no doubt continue to contribute to the geographical enterprise, particularly as the discipline explores the relationship between the human and the physical worlds in addressing environmental concerns.

PARTICIPATORY LEARNING AND ACTION

Participatory development implies an approach to planning and governance that encourages and supports the two-way exchange of information between local communities and outsiders. Participatory development recognizes that community members have valuable knowledge, legitimate concerns, and a lived experience that can contribute to exploring solutions to natural resource-related issues, to planning, and, more broadly, to redressing inequality. Currently, the term is used extensively because of the widespread and growing recognition that participation of local communities in decision making is critical to achieving sustainable development. As a result, community participation has become a central precept underpinning the development agenda.

Fundamental to participatory development practice is a clearly articulated and systematic set of strategies, methodologies, and literature that facilitate community mobilization by community development intermediary organizations (CDIOs) in the execution of local-level decision making. *Participatory learning and action* (PLA) is an umbrella term used to describe these strategies and methodologies. Robert Chambers, a central figure in PLA practice, describes it as a family of approaches, methods, and behaviors to enable poor people to express and analyze the realities of their lives and conditions and then themselves plan, monitor, and evaluate their actions. PLA has been widely used in developing countries to support planning for poverty reduction and is increasingly being employed in the global North in community development projects.

PLA incorporates rapid rural appraisal (RRA), participatory rural appraisal (PRA), and participatory action research (PAR) methodologies and techniques, among others. Yet PLA also can be understood to have grown out of these other methods, each of which represents a distinct stage in the history of participatory development.

RRA was popular in the late 1970s and 1980s. It acknowledged for the first time that experts recognized the need to formally include the poorest members of society in development planning and decision making. RRA offers an approach

and a toolbox that supported development professionals in interviewing community members using low-cost and flexible qualitative research tools (primarily semistructured interviews). The information gathered from these interviews was interpreted by professionals and thus helped inform development intervention.

By the 1990s, RRA had evolved into PRA. PRA focused on development intermediaries working with local communities to identify and articulate development needs through structured group discussions, visualization tools, and other facilitated activities. PRA differed substantially from RRA approaches in that the tools used were more interactive and involved a stronger participatory component.

By the mid 1990s, participatory approaches had evolved into PLA. PLA differs considerably from its predecessors in that it focuses on achieving the full *participation* of local community members in the process of *learning* about their needs and opportunities and in the *action* required to address them. In other words, community members are not simply providers of information that may (or may not) be used to guide development; rather, they are actively engaged as agents of change and are an intrinsic component in planning, implementing, and evaluating development activities. Through interactive learning, knowledge exchange, and flexible yet structured reflection, PLA approaches seek to mobilize local communities and stimulate action that addresses issues of social injustice.

PARTICIPATORY MAPPING

Participatory mapping (PM) is an umbrella term for a broad spectrum of mapping activities. Based to some extent on participatory action research and countermapping, participatory mapping describes mapping projects within which agendas, approaches, processes, techniques, and control rest in some part with the people whose territories and places are being mapped. PM projects have included the mapping of environmental hazards in neighborhoods, the “green mapping” of environmental resources and natural spaces in cities, the mapping of indigenous territorial claims, mapping for resource management, and public participation in zoning and development code mapping.

Other names for PM activities include community mapping, participatory geographic information systems (PGIS), public participation GIS (PPGIS), and participatory rural appraisal (PRA). PM based on three-dimensional (3D) terrain models is called P3DM. Mapping to balance or end control of territory by outsiders is known as countermapping or remapping.

PM projects have taken place worldwide. They have been based on a variety of mapping methods, including sketch maps, 3D models, maps traced from topographic maps, maps drawn on existing base maps, maps based on aerial photographs or satellite imagery, GIS products, global positioning system (GPS) measurements, and Google Earth displays.

Approaches to PM have ranged from grassroots projects instigated, carried out, and controlled by

local groups to top-down, externally funded and controlled projects that have granted only token participation to people from the affected communities. Participation has come to suggest such a wide range of activities and levels of control that PM has recently been viewed with suspicion.

Different levels of local participation range from top-down externally controlled to bottom-up community designed and completed projects. Simply calling a project “participatory,” however, is not a sufficient way to justify a project and does not ensure an appropriate level of participation.

The following are examples of the range of local stakeholder participation:

- Top-down design and control
- Only token local participation
- All decisions made by outsiders
- Maps made by outside experts
- Tasks assigned to community members
- Local people working together with outsiders
- Outsiders and local people sharing knowledge
- Local people setting the agenda
- Local people producing project maps
- No outsiders taking part
- Bottom-up design and control

Important questions that should be asked prior to undertaking a PM project include the following: What is the purpose of the project? Who will pay for the project? What region is to be mapped? Who decides what happens? Who are the stakeholders? Who will be excluded from the process? Who sets the priorities for the project? Who are the “key” informants? Who will learn the mapping skills? How will conflicts be resolved? Who will control the results? How will the maps be disseminated? Who will maintain the maps? Who will be responsible for the future of the project?

The work flow for a typical PM project includes the following steps:

- Recognition of need
- Community request for assistance

- Organizational meetings
- Regional meetings
- Community meetings
- Training workshops
- Pilot projects
- Mapping workshops
- Ethnographic investigations
- Boundary measurements
- Land use measurements
- GIS processing
- Map production
- Ethnography publication
- Technology transfer
- Negotiation for land rights

Land claims may not be successful just because a community makes a map. Maps may have to compete in bureaucratic and judicial arenas with the maps produced by the state or by resource management agencies. Sketches, artistic depictions of place, and 3D models may be useful at various stages of a project, but PM products may have to incorporate coordinate system grids, standardized symbols, and other cartographic conventions to compete with existing maps. GIS offers PM projects the chance to produce high-quality maps that can carry significant weight in court. Some successful indigenous-community PM projects have combined accurate and technically sophisticated maps with ethnographies, drawings, and photographs, presenting a strong case for their land tenure claims.

It should be noted that participatory mapping projects have been criticized as being reductionist and too technical, elitist, and damaging to local conceptions of territory and community. The proposed PM projects can unrealistically raise community expectations. In contested places, the mapping process can expose participants to danger. Without a plan for the future, a PM project can leave a community exposed to threats from the state or from outsiders. Maps construct territory, and so the maps from a PM process can be used and misused. Putting lines on maps where none existed is both powerful and dangerous.

Lands shared by communities can be redefined as contested spaces through a PM process.

The methods selected for a PM project can change ideas of territory. Using GPS to put boundary turning points on maps can exclude distant hunting grounds or seasonal settlements. Surveyors traversing a boundary can assume that traditions of property are the same everywhere. Using existing base maps can give imbalanced weight to features included on standard topographic maps. Map legends that use official languages may have little meaning to participants.

On the other hand, PM projects can empower communities and protect local resources. Local participation can add crucial ground truth that is difficult to obtain in any other way. GPS can be an effective tool for mapping places that may never have been mapped. GIS can aid in the mapping and analysis of subsistence strategies, sacred spaces, community extents, and shared lands. A PM project that is well designed and thoughtfully carried out can combine activism, local knowledge, and community conceptions of place to define, depict, justify, and control territory in a way that can effectively claim space and counter the power of outsiders.

PARTICIPATORY PLANNING

Spatial planning systems across the world influence the places and spaces where people work and live and are deemed to operate in the public interest to ensure that land use planning and development result in more sustainable communities. This is a complex task, given the diverse nature of public, private, and community interests affected by and involved in the planning system and process. Whether it be for ensuring that development occurs where communities need it or for the protection and enhancement of the natural and historic environment and the countryside, planning affects most people. As the outcomes from planning affect everyone, it is widely recognized that community residents should have the opportunity to play a role in delivering effective and inclusive planning. Participatory planning is therefore vitally important for the achievement of sustainable development. This entry outlines the emergence of participatory planning in the 1960s and examines why the current practice of collaborative planning came about and how participatory processes operate.

During the 1960s, there was a dramatic shift in the direction of planning from a post-World War II blueprint model to that of systems analysis and control, which built on the classical work of the British planner Patrick Geddes linking cities to the functioning of ecosystems with a greater need to understand how cities worked. This paradigm focused on four dimensions of understanding the urban system: (1) the role of persistent human activities, (2) the role of human communications, (3) the role of adapted spaces, and (4) the role of communication channels. While human activities and communication channels were highlighted in these approaches, they were very technocratic, and this led to further criticism of the role of the public in planning. Jane Jacobs asserted the view that planners imposed ideals rather than understanding processes and functions. Others provided interesting critiques of these approaches and suggested that an advocacy approach was required, causing a shift in emphasis for participatory planning. The main points of these arguments were that city and regional planners could not be value-neutral technicians, as values are part of every

Figure 1 The eight rungs of Arnstein's participation ladder

Source: Arnstein, S. (1969). A ladder of citizen participation. *Journal of the American Institute of Planners*, 35(4), 216–224.

planning process. Public planners cannot attempt to produce a plan that represents the public interest because of the diverse nature of society. Instead, it was suggested that planning should be pluralistic and should represent diverse interests. An idealized notion of participatory planning therefore needs to encourage people or stakeholders to propose their own plans, with neighborhood groups and other stakeholders involved in the plan preparation and development process.

Sherry Arnstein's famous *Ladder of Citizen Participation* (Figure 1) depicted participation as a series of rungs on a ladder. Her article argues that by recognizing these gradations it is possible to develop a clearer understanding of participation in planning. Since the publication of this article, much of the focus in planning has concentrated on process and has resolved none of the political problems that are inherent in planning. Many believe that planning is a technical discipline and that problems can be solved through a scientific understanding, with planners knowing what is best for the common interest.

Figure 2 The spectrum of stakeholder engagement

Source: Office of the Deputy Prime Minister. (2004). *E-transformation programme: E-planning blueprint* (p. 24). London: Author.

This strategy has not worked, and during the 1980s, there was a shift toward more collaborative forms of planning.

The public participation literature is awash with nuances in terminology, with practitioners often using the following simplistic sequence to describe engagement in planning:

Consultation, through which a basic framework and scope are set and policies or proposals are drafted by the planners, while others (i.e., the community, stakeholders, etc.) are allowed to make relatively minor changes of balance and emphasis

Involvement, in which others have a greater opportunity to debate and influence policies and proposals but probably not the basic framework and scope

Participation, which ensures a more equitably balanced relationship in which others may have an opportunity to debate and genuinely influence all aspects of the process

These processes are often referred to as *collaborative planning*, *stakeholder dialogue*, *consensus building*, *social inclusion*, *holistic governance*, *community capacity building*, *developing social capital*, *partnership working*, and *collaborative advantage*. Models of participation have traditionally been, and continue to be, used to better categorize the participation in planning and planning-related processes (e.g., Figure 2). Stakeholder participation in local communities is often seen as a way in which the so-called democratic deficit of representative government can be overcome, with a greater emphasis placed on participation as an important element in government modernization.

Others have attempted to redesign Arnstein's ladder to reflect the more complicated reality of stakeholder engagement within the policy and planning process. Table 1 rearticulates the ladder in a five-variation model, removing any sense of hierarchy, whereby any of the levels

Source: Adapted from Wilcox, D. (1994). *The guide to effective participation* (p. 15). Brighton, UK: Partnership Books.

could be the correct choice depending on the individual circumstances in which participation takes place.

Further models also demonstrate the differing levels of participation that are possible while still retaining a hierarchical structure with citizen control as the pinnacle of involvement. However, as Figure 3 shows, different types of engagement are appropriate for different occasions and circumstances.

During the 1990s, the notion of collaborative planning began to emerge together with the suggestion that to understand participation in public policy it is necessary to examine the broader governance strategies that institutions may use to achieve differing levels of engagement. These can be categorized into three such strategies. First, *top-down strategies* start and finish with the government agencies that plan such schemes and the local authorities that implement them. Such initiatives occupy the therapeutic and manipulative levels of the ladder, and at best, there can be an element of negotiation. Second, *limited-dialogue strategies* involve a stronger commitment to a two-way communication process. The method and policy framework are set by national and local public bodies but with dialogue that can lead to substantial change in decisions and thinking. The final strategy is the *bottom-up strategy*.

Such a strategy is distinguished by its commitment to open discussion and the active encouragement of excluded or marginalized groups to become involved. In more recent times, the use of information and communication technologies (ICTs) to empower local communities has begun to take hold through the use of online participatory geographic information systems to complement well-established techniques such as "Planning for Real."

Participation in spatial planning has evolved over the past 40 to 50 years, but many of the early protagonists' ideas remain valid today. Despite continuing concerns by some over the potential for participation to cause delays, it has become almost universally accepted as good practice. This has more recently been reinforced by broader conceptual and ideological changes within the public policy arena, as traditional concepts of government have evolved into notions of governance and third-way politics.

PARTICIPATORY RURAL APPRAISAL

Participatory rural appraisal (PRA) is a term used to describe the ever-expanding toolbox of approaches and methods that aim to empower and involve local people in decision making and planning for their future. PRA emerged in the late 1980s and early 1990s as a synthesis of the traditions and techniques of participatory research, whose historical origins lay within applied anthropology and natural resource management. However, it significantly developed most directly from rapid rural appraisal (RRA), a series of techniques that were used by development practitioners and researchers to rapidly collect and analyze data in rural areas. RRA was more extractive by nature, resulting in the emergence of PRA in response to a call for more participatory techniques to enable and empower local people to take control over their own situation. PRA approaches and methods involve local people collecting and analyzing data in projects that are facilitated (rather than controlled) by outsiders. It represents a shift in development thinking from top-down, authoritative approaches to bottom-up planning.

The term *participatory rural appraisal* is somewhat misleading, as PRA approaches can be just as applicable within an urban setting. PRA techniques and methods include, but are by no means limited to, mapping exercises, timelines, cartoons, matrix ranking, diagrammatic representations, and seasonal calendars. These techniques and methods are often broadly grouped into those related to (a) space, that is, the environment in which people are situated; (b) time, that is, time-related dimensions of people's existence; and (c) the relationships within and between various aspects of community life. The focus of PRA is more on the level of engagement with the participants and the attitudes and behaviors of the practitioners involved than the actual techniques themselves. PRA is not prescriptive, but rather, it consists of a range of techniques that are used flexibly and can be adapted for the local context in which they are applied.

PRA emphasizes local knowledge, providing a mechanism by which communities can participate in and direct research agendas. This has resulted in the wide appeal and spread of PRA, particularly throughout the developing world. However, critics point out that while the approaches and techniques draw on local knowledge and experience, the process of identifying these data is carried out through Western theoretical and methodological frameworks. This can contribute to the development of uneven power relations between participants and facilitators and has been referred to as the *tyranny of participation*. The limitations and ethical issues of PRA can vary in their significance depending on the experience of facilitators and on the support of the wider community.

PATCHES AND CORRIDORS IN WILDLIFE CONSERVATION

As human-environment interactions evolve within progressively globalized settings, natural areas become more fragmented, usually embedded in an agricultural landscape. Across varied regions, more than 90% of the natural forest has now been removed, with agriculture and managed lands occupying well over 50% of Earth's land surface. The remaining *patches* of natural habitat can be connected by *corridors* of the same or similar vegetation, providing pathways for the movement of animals and plants and serving, many believe, as a viable conservation tool in the face of continued landscape transformations. Managing such remnants with an eye toward conservation has gained support as one way to stem the impacts of human agency on Earth's varied ecosystems. The connectivity provided by corridors has theoretical foundations and intuitive appeal, but some theoretical ecologists argue against unquestioned acceptance of their conservation value. A recent approach to the patches and corridors scheme contends that the quality of the landscape "matrix" within which patches are found is important and deserving of more attention.

Fragmented Landscapes

Tropical and temperate landscapes both exhibit a high degree of "patchiness" where forest habitat has been left amid an agricultural matrix characterized by pasture lands, fallows, and annual and/or perennial cropping systems. These fragments serve as habitat and may often represent the last hope for safeguarding species in the area.

The challenge to conservationists—often in the face of rampant development—is how best to manage patches in order to maximize and preserve the wildlife they harbor. For a given species, many or all the patches in a region may contain a local population relatively or totally restricted to that patch. The small, isolated populations dotting a landscape in these patches can be grouped together as a *metapopulation*, a term coined in 1969 by Richard Levins, a theoretical ecologist who was thinking about agricultural pests at the time.

As island habitats, patches are likened to true ocean islands, adhering to the theoretical principles and processes of island biogeography. Theory predicts that small patches contain and preserve fewer species than larger ones, and more isolated patches experience higher extinction and lower colonization rates than less isolated ones. Yet with several patches in a region, any given species that goes extinct on one "island" can get reestablished via colonization (the "rescue effect") in other patches—assuming that the organism can get there. Local extinction and recolonization take place within the patches, but the overall metapopulation survives. This is where the concept of corridors comes into play. Corridors form the pathways connecting these patches, and their creation or preservation and maintenance have been recognized and debated as viable ways to protect populations restricted to patches.

The proposed advantages of corridors include the maintenance of metapopulations, the concomitant maintenance of species diversity, the possibility of a rescue effect for any patch experiencing extinction of a species, and greater genetic variability delivered from the metapopulation. Yet homogenization of the total genetic variability throughout the patches could occur, counteracting any patch-specific adaptations that might otherwise develop. Moreover, just as species of conservation concern can move between patches, so too can parasites, diseases, and exotic/invasive species. Though theoretical modeling and empirical observations have focused on the role and potential outcome of these biological corridors, the dearth of reliable data means that the benefits and drawbacks of corridors' true conservation value are debatable.

Evidence From Landscape-Level Experiments

Recent experiments at the landscape level reveal some interesting results related to patches and corridors. In a manipulated landscape in the U.S. state of South Carolina's pine forest habitat, many taxa were found to make use of corridors. Small mammals, bird-dispersed plants, and butterflies showed higher movement between connected patches than between unconnected ones. Other findings associated with this same study area found that pollen transport by butterflies, bees,

and wasps was higher between connected than between unconnected patches, suggesting that corridors facilitate pollen transport in fragmented landscapes.

Corridors can have unanticipated consequences with respect to some organisms. Bluebirds, for example, will travel alongside a corridor without really entering it, dispersing seeds from the fruits they consume. But as “edge-loving” birds, they make use of the edges of corridors, and the corridor’s internal quality matters little. Such results illuminate the concept of “functional connectivity,” which involves not only the pattern and physical arrangement of patches and corridors but the natural history characteristics of the organisms as well. Patch size, for instance, can affect frugivorous birds’ abundance, while patch connectivity can be more important to insectivores. Area, however, is not the sole answer. Time takes a toll as well. Fragments less than 100 ha (hectares) in size can lose more than half their species in less than 15 years. A “large enough” patch seems to be at least 1,000 ha, a sobering thought since such large areas in species-rich regions are so scarce.

The Matrix Matters

Connectivity can aid in the movement of primates, birds, small mammals, and several other taxa. But it has little to do with corridors and more with the matrix. The matrix has often been considered a featureless expanse across which organisms must find their way. Yet many terrestrial landscapes display great variability in terms of the interpatch milieu.

A low-resistance matrix will tend to allow a relatively easy passage of organisms from one patch to another. A high-resistance matrix, in contrast, restricts travel between patches. Organisms that are generalists (i.e., they are able to exist in a variety of habitats and can take advantage of a wide variety of resources) would likely have few problems in going from patch to patch across a landscape mosaic. But a ground-feeding species specializing on resources found in a dense understory might never brave the quiltwork-patterned matrix around its “home patch.”

A matrix highly resistant to one organism may pose little problem to others—the reasons for

which may be subtle. For instance, an antshrike bird (a forest specialist) in a tropical fragmented setting uses riparian or gallery forests (relatively narrow corridors) to move between patches of dry forest in the fragmented landscape but tends to avoid pastures and living fence rows (mixed tree species planted along roadsides). In contrast, a rufous-naped wren (a forest generalist) moves through the matrix by using the thin linearity of fencerows without hesitation.

Recent meta-analysis of data from more than 1,000 population networks of mammals, birds, reptiles, amphibians, and invertebrates on six continents evaluated the effect of habitat area, isolation, and the matrix itself. A central conclusion is that patches are less like islands than some might think. The size and isolation are indeed important factors determining species presence, but the matrix in which patches are embedded must not be ignored.

PATH DEPENDENCE

The concept of path dependence has been popularized by economic historians and is now widely employed in economics, history, political science, sociology, and geography to describe systems and processes that are governed by their own history. More formally, a path-dependent system or process is characterized by *nonergodicity*, a term taken from the theory of stochastic systems. While an ergodic system or process will converge toward an invariant, asymptotic probability distribution regardless of its initial conditions, the asymptotic probability distribution of a nonergodic or path-dependent stochastic system evolves as a consequence of its own history. Path dependence is a label for a particular class of dynamic systems or processes, not a theory explaining how those systems behave. It is thus necessary to “develop theories and frame hypotheses regarding the economic circumstances in which path-dependent dynamics are likely to appear, and where the consequences of past events can be expected to exert greatest and most enduring influence” (David, 2007, p. 92).

Work on path dependence differs in the emphasis that scholars give to four elements included in most accounts: “causal possibility, contingency, closure, and constraint” (Bennett & Elman, 2006, p. 252). Causal possibility means that more than one path could have been taken at a specific historical juncture. If we could rerun history and end up with the same outcome every time, then that process is not path dependent. Some authors argue that early events are more important than later events in the sequence, while others distinguish between path independence and path dependence, where the former refers to those outcomes that are independent of the order of events. Contingency entails that the causal narrative be influenced by random or, in some cases, exogenous events. Closure refers to the fact that once a path is chosen, alternative paths become increasingly unlikely. And finally, once a path is chosen, a constraint is required that ties agents to that path.

In economics, three main versions of path dependence exist: path dependence as a technological lock-in, as increasing returns, and as institutional hysteresis. Paul David’s work on technological lock-in highlights the impact of contingent *accidents*, or microlevel chance events, on long-run trends and structures and stresses the importance of early events or decisions for closing alternative paths and strengthening existing ones as network externalities increase the efficiency gap between the chosen and the abandoned paths. The lock-in of suboptimal designs and systems such as the QWERTY keyboard or the VHS video system is often invoked as proof that markets do not necessarily lead to optimal outcomes. Brian Arthur’s work highlights the role of various forms of increasing returns to explain how a technology or spatial system becomes locked into a path. Arthur formalizes those processes through the so-called ball-and-urn models to demonstrate how macrostructure emerges from contingent, random micro events and behavior. Mark Setterfield’s work on institutional hysteresis recognizes that formal and informal institutions, such as conventions, habits, and traditions, change only slowly over time; structuring human behavior, interaction, and communication, these institutions keep people, places, and countries on specific evolutionary trajectories. The work suggests that the adopted technologies, spatial patterns, or

Figure 1 Development path of a regional system

Source: Adapted from Martin, R., & Sunley, P. (2006). Path dependence and regional economic evolution. *Journal of Economic Geography*, 6, 395–437.

institutions are not necessarily the most efficient alternatives. The work also stresses that the past does not determine the future but that at each moment in time, the possible future evolutionary trajectories are contingent on the past and current states of the system in question and some paths are more likely than others.

The concept of path dependence holds considerable promise for characterizing the evolution of spatial systems. Geographers have long argued that economic landscapes are the legacy of their industrial and institutional history. Once industries settle in particular places, the sunk costs, external economies, and coevolving institutional environment lock the place into a particular evolutionary trajectory. While the actualized location pattern is one of many probable ones, once contingent events confer initial advantages or disadvantages to a region, externalities will produce long-enduring patterns of uneven spatial development. Existing levels of inequality are thus long enduring but may be shaken up at so-called bifurcation points, when fundamental changes in

technological paradigms, macroeconomic shocks, or government intervention reshuffle the spatial hierarchy.

In geography, path dependence is often equated with regional lock-in. The metaphor of lock-in captures the quasi fixity of patterns of economic specialization and uneven development through strong positive and negative feedback processes. Most discussions of regional lock-in refer to the growing rigidification and declining adaptability of regions to changing economic conditions. But while lock-in is primarily understood as negative lock-in, some regions are able to propel themselves along long-enduring growth trajectories. Both forms of lock-in exist. While some regions, such as the Boston or London metropolitan areas, are able to continually reinvent themselves and remain on a growth trajectory, others, such as the Ruhr area, miss critical historical junctures such that a positive lock-in turns into a negative lock-in. Figure 1 illustrates how past choices and the present system state both enable and constrain, but do not determine, future states and

pathways. Once decisions have been made and pathways have been chosen, new possible paths open up and others close down.

There are some obvious problems with the concept of path dependence in general and with its application to spatial evolution in particular. Different authors distinguish between different types, degrees, and causes of path dependence. A narrow definition would enhance the conceptual clarity but exclude a number of interesting cases, even if the observed process is clearly history dependent. Furthermore, the distinction between path dependence and lock-in is ambiguous. For some, lock-in refers to the trapping of a system or process in an equilibrium configuration from whence only exogenous forces can recover it. According to this definition, path dependence would be inconsistent with evolutionary explanations, as evolution proceeds through the endogenous transformation of systems. The application of path dependence in geography is further complicated by the fact that a region is an ensemble of agents, technologies, firms, institutions, networks, and interdependencies, and as a result, it is unclear what the object of study is or how different path-dependent processes inside and outside the region and at different scales interact. It is also unclear why, how, and when regions become locked in and how new technological, industrial, institutional, or regional paths are created. While path dependence and lock-in can help us understand the evolution of a system once a path is chosen, they say little about the creation of new paths. Usually, their emergence is simply attributed to chance or historical accidents rather than derived from past and present economic conditions. But this type of reasoning is unacceptable since “the whole point of path-dependence is to restore the importance of causal, historical economic explanation involving sequential actions; placing too much emphasis on random accidents as the sources of path creation constrains and undermines such causal explanation” (Martin & Sunley, 2006, p. 428).

PATRIARCHY, GEOGRAPHY AND

Patriarchy refers to a set of hierarchical power relations between men and women in which men are able to dominate women and masculinity is privileged over femininity. Such gender domination takes place at all levels of social interactions. While intersecting factors such as race, class, sexuality, and ethnicity may place men and women at different levels of the power hierarchy, patriarchy unites men in their domination over women across place and time. Patriarchy is not a random hierarchical system but rather a system in which women are particularly oppressed and their roles devalued or undervalued. Patriarchy is therefore systemic and has led to the material and ideological oppression of women and the marginalization of femininity while simultaneously benefitting men and attributes considered masculine. As a

foundational concept in the study of feminist geography, patriarchy historically places the sex/gender system as the central object of analysis in social relations. In the past 20 years, however, feminist geographers have increasingly favored analyses that focus on interlocking systems of power that include but do not privilege gender. Analyses of patriarchy are necessary in a number of fields in geography, including economic, cultural, and political geography as well as geographies of sexuality and race/racism.

In a pivotal article in feminist social theory, Heidi Hartmann outlined the main elements of patriarchy as heterosexual marriage and heterosexism or heteronormativity, female care work and household labor, women's economic oppression in the paid labor market, the state and governmentality, and diverse institutions that promote and privilege social relations among men such as the military, churches, universities, sports clubs, and the professions. While offering a closely connected list of locations of patriarchal relations, the sociologist Sylvia Walby also added the realms of sexuality and male violence as important sites of male dominance over women. Her analysis of patriarchy divides these sites into a domestic regime, which occurs primarily in the private sphere, and a public regime, which pertains to the courts, the government, and the formal labor market. Other examples of patriarchal power and control include domestic violence and sexual assault, the gendered division of labor, and discourses on motherhood and care work that promote women's unpaid labor in the home.

Some view patriarchy as universal and separate from other systems such as capitalism, while others believe that patriarchy takes on different forms and changes in particular economic, political, and social settings. Within feminist geography, these positions are defined as the dual-systems model and the single-systems model. Some have argued that patriarchy and capitalism are distinct and separate phenomena, while others believe that patriarchy exists as a result of capitalist modes of production and reproduction. These debates, which took place among feminist geographers in the pages of *Antipode* in the mid 1980s, gave rise to further discussions and connections concerning the relationship between

patriarchy and sexuality, patriarchy and race/racism, and patriarchy and ethnicity, to name a few.

These debates also highlighted the differing views of gender within feminist geography. By the mid 1990s, many feminist geographers argued that gender was not a single category but a limited and fractured analytical and material one. Patriarchy as a hierarchical system was therefore decentered, as feminist geographers explored the contextuality of patriarchal relations and the importance of overlapping, interlocking, or intersecting relations of power and domination. Importantly, this work has offered new subjectivities of women not simply as victims of their gender but also as actively engaged and not merely oppressed. For geographers, this means distinguishing between forms of patriarchy across space and place and illustrating the fluidity of power and hierarchies.

Within geography, subdisciplines such as economic geography, political geography, cultural geography, and sexuality studies have used the concept of patriarchy in their analyses and research. The works of Doreen Massey and Linda McDowell in economic geography describe how economic restructuring in Britain greatly changed the gendered division of labor and produced differences across regions. In their study on contrasting colliery and cotton villages in Northeast England from the 19th to the 20th centuries, the gendered division of labor was based highly on patriarchal discourses of women's labor and economic worth. In another example, Michael Brown and Lynn Staeheli's work in political geography highlights how feminist geographers use concepts such as patriarchy to deconstruct and reinvent distributional, antagonistic, and constitutive approaches to space and power. Finally, work in the sexuality and space literature and cultural geography critiques how the discursive dominance of the nuclear family and heterosexual marriage enforces heteronormativity and marginalizes other forms of familial relationships.

PEASANTS AND PEASANTRY

Peasants are small agricultural producers, especially in less industrialized countries, who possess their own land and who use relatively simple equipment and family labor to produce mostly for their own consumption. All peasants are involved in markets, some much more than others. They live in small rural communities, although they often interact with towns, where they sell their products and buy what they need to farm and live.

Known collectively as the peasantry, peasants have existed for millennia as the majority of humankind until very recently. Peasants have lived in a large variety of historical and geographical contexts. Originally possessing land on which they supported themselves, peasants have frequently lost their land, water, and forests and have been forced to work as wage laborers. This process has been intensified with the evolution of neoliberal capitalism. Their status within capitalist economies varies, and they can be differentiated into rich, middle, and poor peasants, respectively, depending in part on whether they retain property, hire labor, or work as wage laborers themselves.

The study of peasants has been institutionalized through the establishment of interdisciplinary journals such as *Journal of Peasant Studies* in the early 1970s. The 1970s marked a resurrection of peasant studies following a quarter of a century in which the field had been relegated to relative obscurity. Peasant impoverishment and

insurrection in the Third World became important academic topics. Peasant studies occupy an interdisciplinary intellectual space. In scholarly discourses in general, and within human geography in particular, peasants have appeared in discussions of uneven economic development, including the transition to capitalism in Europe and in the Third World; of environmental change and political ecology; and of social protest, identity/agency, and the state. In terms of social theory, peasants have often been at the center of debates between Marxism and postmodernism/poststructuralism. Many of these themes are mentioned in this entry, which focuses on three areas: (1) whether peasants constitute a separate society/culture/economy; (2) the impacts of capitalism on peasants; and (3) peasant identity/agency and political action.

Peasants as a Specific Type of Society, Culture, or Economy

For many scholars, including supporters of modernization theory and populism, peasants constitute a separate type of society, culture, or economy. Important concepts in the modernization tradition are Robert Redfield's folk culture and George Foster's idea of limited good. According to Redfield, peasant communities are a kind of folk society that exists on a folk-urban continuum, where cities represent its modern urban end and peasant communities are placed near the other end. In the "limited good" model, in peasant societies, sources of income such as land and market opportunities are scarce, leading to stiff competition for such resources. On this basis, there arises a specific peasant moral and ethical imagination. Envy, fatalism, individualism, and fear of witchcraft are often parts of a specifically peasant worldview, which impedes development-as-modernization.

Some scholars (e.g., Daniel Thorner and Teodor Shanin) have used the term *peasant* to define an economy constituted by self-sufficient peasants. When Marxists refer to peasant society, as in pre-industrial Europe, they refer to class relations between peasants and feudal landowners. In a peasant society, the basic aspects of rural economic organization, such as landholding size, food output, and work motivation, are governed

Peasant farmer carrying straw on a rake in Hoi An, Vietnam

Source: Benjamin Schepp/iStockphoto.

by the size of the peasant family, the ratio of working to nonworking family members, and the necessity to meet the family's subsistence needs. Chayanov's view of a homogeneous peasantry composed of self-sufficient petty-commodity producers who are able to subsist through family labor and forced underconsumption—which constitutes a pan-historical socioeconomic category—is contradicted by the Marxist process-oriented view stressing peasantry's internal class differentiation. Critics say that peasants cannot constitute a separate economy because they have existed in a variety of historically existing modes of production including feudalism and capitalism.

Peasants and Capitalist Society

Capitalism affects peasants in various ways, including primitive accumulation, peasant differentiation, and articulation and subsumption.

In the process of what Karl Marx called *primitive accumulation* or what David Harvey calls *accumulation by dispossession*, peasants are forcibly evicted from their property (land and forests) and forced to work for private employers. An example of this process is the Enclosures Acts of early modern England, which drove many peasants into urban areas. In recent times, this process has intensified with the establishment of special economic zones created on farmland.

In the process of peasant differentiation, which occupied a prominent place in Lenin's works, the class of archetypical peasants (those who grow crops on their own land using family labor) is differentiated through the impact of market relations and technological change (e.g., the Green Revolution promoted by transnational corporations). Peasants face market competition from larger farms at the national scale and from global agribusinesses, particularly subsidized

U.S. firms. When peasants are involved in market relations, those who are resource-poor are disadvantaged because of factors such as shortage of household labor, sudden crop failure, or a sudden change in the prices of crops and inputs. They may have to borrow money at high interest rates. Over time, they may be forced to sell a part of their land to clear the debt; in the process, they may completely lose their land and become landless laborers. Some even commit suicide due to the unbearable burden of debt. When peasants are left with some land that is not sufficient for their subsistence, they are called poor peasants; apart from working on their tiny plots of land, they work mainly as tenants/sharecroppers by paying a rent and/or working as wage laborers. Peasants who do better economically may buy land and become rich peasants; they still use family labor, but most of the labor used on their farms is hired labor. Some rich peasants over time become capitalist farmers. Middle peasants—archetypical peasants—do not usually hire laborers (except in peak seasons) or hire themselves out. Thus, the peasantry tends to be differentiated into three classes of peasants (rich, middle, and poor peasants), suggesting that it is not a homogeneous class.

The extent of differentiation may have been exaggerated in the classical Marxist model. Middle peasants may not be completely separated from their land. The process of differentiation can be very slow. Some peasants can hold onto their land by decreasing their costs of maintenance and through state subsidies and remittances from city-based family-members. However, although this differentiation may take place slowly, it does occur; peasant-based production is undermined by more efficient farm production nationally and internationally, and peasants do become laborers. But peasant differentiation is uneven as market penetration and state support vary. Because of the geographical variation in the extent and the effects of peasant differentiation into poor, middle, and rich peasants with differing capacities for investment, understanding this geography is an important aspect of our understanding of uneven development as such.

In the third view of peasant-capitalism relations, which is based on the French structuralist

school, the precapitalist peasant communal mode of production is integrated into the capitalist mode of production in a subordinate relation, that is, in a marginalized status. This process happens geographically, that is, the circular migration of peasant-laborers. Precapitalist peasants as migrants are a source of cheap labor power for city-based capital. Their labor power is cheap because a part of the cost of its reproduction is borne by their household production in villages, one in which women are particularly involved. Indeed, the gender division of labor—where females produce subsistence foodstuffs within a noncapitalist mode of production and semiproletarianized males work for urban capital—makes it possible for capitalists to pay migrants a male wage rate that is insufficient for familial maintenance. The form of integration between capitalist and noncapitalist modes of production occurs at an international scale, that is, an extraction of surplus value from the latter, and transfers to the rich countries through colonialism and imperialism.

Finally, capital can subsume and exploit peasants as commodity producers as it does industrial workers. Peasants exist not outside capitalism but as an integral part of it; peasants are not precapitalist. Peasants, many of them women, use their labor power to produce commodities for the market. The price they receive from buyers (e.g., merchant capital) is less than the full value of their labor power because of unequal exchange (low farm prices and high input prices). The surplus value extracted contributes to capital accumulation in the city.

A specific form of subsumption happens through the impacts of agribusiness, which include credit, inputs, and extension services. Agribusiness firms lay down technical conditions and provide a market to peasants for a predetermined price. In contract farming, about which geographers such as Michael Watts have written, it is as if peasants-as-laborers in some places are working with other people's means of production. Some who benefit financially may attain the status of agrarian capitalists. But ultimately, the profits of agribusiness as well those of richer peasants and rural capitalists are based on the exploitation of poor peasants and landless workers working on contract farms and on the intensive

exploitation of the land and water (or aquatic) resources.

Peasants have become a part of capitalism in another way. With the spread of neoliberal capitalism, there is a tendency toward de-agrarianization of peasants, as the latter are increasingly involved in nonagricultural activities. These include petty trading and wage labor in industries, at least as part-timers. Dispossessed of their land and finding farming unviable (because of the withdrawal of state support under neoliberalism), peasants indeed have become a part of the global reserve army of labor waiting to be hired when capital needs them. As a result, there is pressure on the wages of those currently employed, with many poor countries (with massive peasantries) becoming a profitable destination for transnational corporations. Sometimes agribusinesses also appropriate peasants' knowledge about nature and farming.

Peasant Identity and Agency

As far as peasant agency is concerned, peasants are often considered to be both conservative and revolutionary. The conservative peasant, said Karl Marx, wants to consolidate his or her small holding. Smallholding peasants do not form a class that is explicitly conscious of its interests vis-à-vis the exploiting classes; rather, they constitute a mass of people lacking any potential for class action. But it is widely known that peasants did play heroic roles in antifeudal struggles in Europe. Similarly, Mao Zedong brought peasants to the center stage in China, both in practice and in theory through his writings. Also, some of the welfare-oriented programs of post-colonial capitalist states (e.g., redistributive land reforms) have been implemented because of peasant movements and, of course, with the aim of creating a national market that includes peasants as consumers.

There are at least two views concerning the source or origin of peasant agency/identity. In the non-Marxist literature, including that which is postmodern/neo-populist, peasants are seen as a homogeneous class having an innate identity, a subaltern "peasantness," that prompts them to pressure for changes inside capitalism. Peasant agency is also seen as the use of networks at

different geographical scales as a survival strategy in an exploitative society, rather than as advocacy of a revolutionary agenda.

In the post-Marxist critical peasant literature, peasant agency is looked at through the lens of class differentiation. In this view, peasants have several class-based identities. Different classes of peasants will have different kinds of agency. Middle peasants are economically independent and have greater potential for revolution than other peasant classes. Poor peasants are initially the least militant because of their dependence on landlords or rich peasants for land-on-rent, for wage work, and for loans. But in a revolutionary situation, when middle peasants mobilize themselves against landlords and rich peasants, the morale of poor peasants is raised, and they are ready to respond. The middle peasants are initially the most revolutionary, but when the revolutionary action intensifies, they vacillate about whether to persevere because of their stake in the private property system, unless their fears of losing their livelihood are allayed. Critics of this thesis say that middle peasants do depend on landowners for credit and are heavily attached to their land, making them a weaker revolutionary force than other classes. On the other hand, poor peasants (along with landless peasants as laborers), since they are the most exploited and as they form the majority of the rural population, are the most revolutionary.

In reality, peasant movements are often multi-class. Leaders of middle and rich peasants (and capitalist farmers) mobilize the entire peasantry to lobby for benefits such as more input subsidies and higher output prices. An important form of multiclass mobilization is action against landlords for land and against the capitalist strategy of state-supported primitive accumulation (the threat of dispossession of their land in the name of national industrialization/development). Multiclass mobilization of peasants is seen as problematic on many grounds. When the interests of better-off peasants are met (e.g., land is obtained from the landlords), they often withdraw from the movement. When multiclass mobilization successfully puts pressure on the state for higher food prices, such increases do not benefit poor peasants and landless peasants, who are net buyers of food. In this and many other ways, multiclass

action also de-emphasizes the interests of poor peasants and landless laborers as classes. It mobilizes social constructions of democracy, culture, and identity in ways that are unspecific in terms of their class content and are therefore populist.

Peasant agency and resistance have taken various forms. Banditry, viewed as a kind of peasant protest, has been studied by Eric Hobsbawm. It targets lawyers, moneylenders, traders, and foreigners, who are seen as oppressors. Another form of individual action is said to be the everyday form of resistance, which has engaged the attention of James Scott and others researching peasants in the tradition of the historian E. P. Thompson. Here, peasants are seen as making use of the so-called weapons of the weak, including foot dragging, desertion, false compliance, pilfering, slander, arson, and sabotage. These are reinforced by a popular culture of resistance. These forms of class struggle require little or no coordination, make use of impersonal networks, represent a form of individual self-help, and avoid direct confrontation with authority. In terms of the goals of peasant protests, these scholars also emphasize the moral economy aspect; protests tend to be focused mainly against landowners who do not respect their need to earn a subsistence income.

These views have been criticized for de-emphasizing the importance of the conscious construction of radical ideology and organizational structures to mobilize peasants. They also inaccurately essentialize peasant resistance, that is, by asserting that peasants necessarily make use of the “weapons of the weak.” It has been said that if peasants become conscious of their exploitation, they will fight against capitalism in an organized manner. Peasants have been mobilized by communist parties all over the world. An important aspect of peasant mobilization is the peasant-worker alliance, represented by the hammer and sickle in communist party symbols. If capital can exploit peasants, as it does property-less labor, by exploiting them without dispossessing them of their property, a space for a collective revolutionary alliance between workers and peasants against capital opens up. Peasants also launch organized protests against the capitalist state (including in a colonial situation), for the state acts on behalf of (foreign) capital and makes demands on peasants for resources (such as money, unpaid labor, and

in kind) for developmental interventions and war making. Corrupt, coercive, and oppressive government officials tend to be peasants’ targets, as India’s continuing Naxalite movement, which is informed by Maoism, testifies. In this context, the dialectics of the state-peasant relation is worth mentioning. To the extent that the state has played the role of trusteeship in national capitalist development, peasants seem to have suffered both when there is what the geographer Nanda Shrestha calls “failed development” (leading to, e.g., low productivity, unemployment, and low wages) and when development “succeeds” (leading to development-induced displacement, price inflation, and indebtedness). Peasants have responded partly by fighting against both large owners of property and the state.

Peasant movements are not just “economic.” Some radical scholars argue that a new form of peasant movement is emerging (new peasant movements, or NPMs). Although rooted in rural struggles, the participating peasants in NPMs are educated, are connected to the cities (where they used to be ex-miners or displaced workers and where they receive regular ideological/political training), and have a cosmopolitan view. Often independent of political parties, they engage in direct struggle rather than electoral fights. They reject economistic class analysis, but neither are they focused on issue-based identity politics. Thus, they are influenced by a mixture of Marxism and by ideas related to ecology, ethnicity and nationality, and gender. They coordinate their struggles for economic progress, democracy, autonomy, and dignity at multiple geographical scales, including the international.

Peasants have been exploited by large agribusinesses (contract farming being a specific example). In many different contexts, peasants and property-less laborers continue to engage in political actions against capital, domestic or foreign. They have also occasionally fought against the state (e.g., Mexico’s Zapatistas). As the crisis-prone nature of the capitalist system plays out differently in different countries in the global periphery, the specific ways in which various classes of peasants and rural laborers are affected, and how they respond, will vary considerably.

PEAT

Peat is an organic deposit formed on Earth’s surface under waterlogged conditions. In most soils, dead organic matter is consumed in the presence of oxygen by organisms such as invertebrates, fungi, and bacteria about as quickly as it is added through processes such as leaf fall and plant death. The organic matter is oxidized to carbon dioxide gas and water, and over the long term, the amount of organic material in the soil hardly changes. However, if the sediments are waterlogged, oxygen becomes scarce because gases diffuse much more slowly in water than in air and the oxygen that is consumed cannot quickly be replaced. In the absence of oxygen, decomposition is slower and incomplete. This leads to the buildup of peat. Peat thus consists of partially decomposed remains of plants (and, in much less abundance, animals) that previously lived at the site of deposition. It may also contain small amounts of material such as wind-blown dust and chemical precipitates. (Most authors draw a distinction between in situ peats and organic lake sediments containing plant material that may have originated at some distance from the location of the deposits.)

Peat deposits are found in all but the most arid environments. Tropical peats tend to occur in basins, river deltas, sheltered coastal mangrove swamps, or estuaries—anywhere where water flows slowly enough to allow stagnation and anoxia to develop. At higher latitudes, peats frequently grow above the regional water table because certain peat-forming plants, chiefly *Sphagnum*, are able to retain water like a sponge; such peatlands are called raised bogs. At very high latitudes, the low temperatures and the presence of seasonal snow and ice can aid waterlogging in reducing decomposition rates.

Peatlands are ecologically important. Peatlands fed by groundwater are often very productive and can have high biodiversity. In contrast, raised bogs, being fed only by rainwater, tend to be acidic and poor in nutrients, with a highly specialized flora and fauna. As peat accumulates, it effectively records its own history in the form of layer upon layer of subfossilized plant and animal remains. Ecologists are able to use this information to

Men cutting peat from a bog in Maamturk Mountains near Cong, Ireland

reconstruct the long-term development of these ecosystems.

Peatlands are estimated to cover more than 4 million square kilometers, or 3%, of the land surface of Earth and contain approximately one third of all carbon stored in soils. Peatland destruction may therefore contribute to the increasing concentration of carbon dioxide in the atmosphere and hence to global warming. However, peatlands also produce methane as a by-product of the decomposition processes. Methane is a much more powerful greenhouse gas than carbon dioxide, so the net effect of peatland loss on the climate system remains unclear. Climate change may itself upset the carbon balance of high-latitude peatlands, for example, by causing drying out and increased oxidation of organic matter, so peatlands may turn out to act as a positive feedback within the climate system.

The major cause of destruction of peatlands in the recent past has been drainage for forestry and agriculture; about 10% to 20% of the world's peatlands have been destroyed since AD 1800. Peat also has a range of commercial uses, notably as a fuel for heat and electricity production and in horticulture, and it is widely extracted for these purposes.

PEET, RICHARD (1940–)

One of radical geography's most passionate and vociferous promoters, Richard Peet has devoted his career to exposing the ways in which power and inequality are manifested in global society. Although in some senses Peet's career reveals remarkable consistency and stability—since receiving his PhD at the University of California, Berkeley, in 1968, he has been a professor at Clark University, and his commitment to Marxism has been unwavering—the focus of his analysis has shifted over the decades.

Peet was an early promoter of Marxism in geography, founding the radical geography journal *Antipode* in 1970, which he edited until 1985, as well as editing an early collection of radical geography essays in 1977. Peet's own version of Marxist geography had (and continues to have) a strong environmental focus, as he sees Marxist geography as particularly well suited for understanding the social conditions that arise out of the productive transformation of nature. This focus has led him to forge strong links with political ecology and development studies, two areas of geography that attempt to understand how nature is transformed at the local scale and how the extraction and transformation of nature are organized globally.

In the 1980s, Peet was on the frontlines of a battle between Marxists and postmodernists, whose understanding, in Peet's view, was insufficiently grounded in the material conditions of production and reproduction. Waging this battle drove Peet deeper into geographic thought and its philosophical underpinnings, as well as leading him to alternative theories of culture and meaning, culminating in the publication of *Modern Geographical Thought* in 1998.

The 1990s saw Peet return to his core interests in the global economy and in the relationship between nature and society, but now from a theoretical perspective that, although still rooted in Marxism, incorporated a broader range of

theorists, notably Cornelius Castoriadis and Michel Foucault. His work in international political economy and development theory led to the publication of *Global Capitalism* (1991) and *Theories of Development* (coauthored with Elaine Hartwick, 1999/2008), while his work in political ecology resulted in the publication of *Liberation Ecologies* (coedited with Michael Watts, 1996/2004).

In the 21st century, as countries throughout the world abandoned socialist development strategies, Peet shifted his focus to the global institutions through which neoliberalism permeates the decisions made by governments, corporations, and individuals around the world. A collaborative research project with a collective of undergraduate students resulted in the publication of *Unholy Trinity: The IMF, World Bank, and the WTO* (coauthored with 16 students, 2003) as well as his book *Geography of Power: The Making of Global Economic Policy* (2007).

Whether huddled with graduate students pasting up copies of *Antipode* in the basement of Clark University, inciting students to think about the geographies of power in their lives, or challenging a speaker at a professional meeting, Peet brings an exceptional level of enthusiasm and passion, as well as academic rigor, to radical geography.

PENCK, WALTHER (1888–1923)

Walther Penck was the son of the famous German Quaternary scientist and geomorphologist Albrecht Penck. Albrecht had both a professional and a personal relationship with William Morris Davis that eventually became acrimonious. Walther Penck's claim to fame as a geomorphologist rests on the posthumous publication by his father, in 1924, of his book *Die morphologische Analyse* (*Morphological Analysis*). Written in highly convoluted German, it received very little attention in Germany but became a central and contentious topic within the English-speaking world of geomorphology due to what some perceived as a self-serving interpretation by Davis. This article remained the authoritative English source of Penck's ideas until Hella Czech and Katharine Cumming Boswell published an English translation of the work 40 years later.

The idea in Penck's work that received so much attention in the English-speaking geomorphologic world was that of the parallel retreat of slopes. Such a pathway would produce an entirely different history of both slope and landscape development from that proposed by Davis, whose convexo-concave slope profiles decline in angle with time and whose landscapes become peneplains. This alternate view of slope development became most significant in Lester King's description of landscape development that produces pediplains, not peneplains. While King and others assigned the concept of parallel slope retreat to Walther Penck, this is a misconception that was first found in Davis's interpretation. Penck initially launched his ideas cautiously, apparently trying to avoid direct conflict with Davis, but later he became more openly critical of Davisian ideas.

The reality is that Penck produced a very logical and internally consistent model of slope development that argued not for the parallel retreat of slopes but for slope replacement extending upslope from the base. However, the slope model was not Penck's primary objective; his real objective was to investigate tectonic, or crustal, movements, which he attempted to do by relating surficial form to subsurface activity. He tied his ideas on slope form closely to local tectonic

history and synthesized his views on individual slopes to produce regional assemblages such as *Piedmontreppen* (stepped erosional benches) and *Primarrumpf* (primary peneplains). Complicated German and an early death left many of Penck's ideas undetermined in detail within the English-speaking world, making him a major figure in English language geomorphology and a minor one in his native Germany.

PERIGLACIAL ENVIRONMENTS

Periglacial environments are characterized by intense frost, often combined with the presence of perennially frozen ground, or permafrost. Periglacial environments are restricted to areas that experience cold, but essentially nonglacial, climates. They include (a) the polar deserts and semideserts of the High Arctic and the icefree areas of Antarctica; (b) the extensive tundra zones of high latitudes; (c) the northern parts of the boreal forests of North America and Eurasia; (d) the alpine zones that lie above the timberline and below the snowline in mid- and low-latitude mountains; (e) the high-elevation montane environments of Central Asia, the largest of which is the Qinghai-Xizang (Tibet) Plateau of China; and

(f) small oceanic islands in the high latitudes of both the polar regions.

In climatic terms, periglacial environments are areas where the mean annual air temperature is less than +3 °C. This can be subdivided into environments where frost action dominates (mean annual air temperature less than −2 °C) and those areas in which frost action occurs but does not necessarily dominate (mean annual air temperature between −2 °C and +3 °C). Fundamental to most periglacial environments is the freezing of water and its associated frost heaving and ice segregation.

Periglacial environments occupy approximately 20% of the world's land area. However, their human population is only 7 to 9 million, mostly living in Russia, or only 0.3% of the world's population. Thus, the larger importance of periglacial environments lies not in their spatial extent but in their natural resources. For example, the old Precambrian basement rocks that outcrop as huge tablelands in both Canada and Siberia contain precious minerals, such as gold and diamonds, and sizable deposits of lead, zinc, and copper, while the sedimentary basins of Western Siberia, Northern Alaska, and the Canadian High Arctic contain large hydrocarbon reserves. A second reason why periglacial environments are of significance is their place within the cryosphere (i.e., snow, ice, frozen ground, sea ice) and the critical role that the cryosphere plays in global climate change.

Periglacial Ecosystems

The most extensive periglacial environments are those of the high northern latitudes (Figure 1). These can be regarded as either arctic or subarctic in nature. The boundary between the two approximates the northern limit of trees, the so-called tree line. This is a zone, 30 to 150 kilometers in extent, north of which trees are no longer able to survive. North of the tree line, the terrain is perennially frozen, and the surface thaws for a period of only 2 to 3 months each summer to depths that, in vegetated areas, may be as little as 30 to 50 centimeters. Ecologists refer to the vegetated but treeless arctic as tundra (see lowland tundra photo). Where Precambrian basement rocks occur, as in the tablelands of Northern Canada

and Siberia, the tundra is barren. At higher latitudes, the tundra progressively changes into semi-desert and, ultimately, into polar desert terrain (a “frost-rubble” zone) in the high latitudes of Arctic Canada, Northeast Greenland, Svalbard, and Novaya Zembya.

The alpine environments of the midlatitudes are less extensive but equally distinct, being dominated by both diurnal and seasonal effects and by much higher solar radiation. In such environments, the timberline constitutes the boundary between the alpine and subalpine. Alpine environments are dominated by steep slopes, tundra (alpine) plants, rock outcrops, and snow and ice. The montane environments of Central Asia differ from the alpine environments in that they are more extensive, are far more arid, and consist of steppe grasslands and intervening desert-like uplands. In Antarctica, the relatively small ice-free areas are unusual, being essentially polar deserts or rock-rubble surfaces that are kept free of snow and ice by sublimation from strong katabatic winds that flow outward from the Antarctic ice sheet.

The tundra and polar deserts of both North America and Eurasia contain a surprisingly large number of plants and animals, given the severe climatic constraints. For example, large mammals such as the polar bear, musk ox, and fox are all present, although the number of mammals and plant species progressively increases southward in the tundra. In the subarctic, two major ecological zones can be recognized (see tundra photo). Near the tree line is a zone of transition from tundra to forest consisting of either open woodland or forest tundra. Here, the trees are stunted and deformed, often being less than 3 to 4 m (meters) high. Woodland caribou and grizzly bear replace the polar bear and musk ox. This zone grades into the boreal forest, or taiga, an immense zone of almost continuous coniferous forest extending across both North America and Eurasia. In North America, the dominant species are spruce (*Picea glauca* and *P. mariana*). In Siberia, the dominant species are pine (*Pinus silvestris*) and tamarack (*Larix dahurica*). The southern boundary of the subarctic is less clearly defined than its northern boundary; typically, coniferous species begin to be replaced by others of either local or temperate distribution, such as oak, hemlock, and beech, or

Figure 1 Regional extent of the periglacial domain in the Northern Hemisphere

Source: French, H. M. (2007). *The periglacial environment* (3rd ed., Figure 1.5, p. 12). Chichester, UK: Wiley. Copyright © 2007. Reprinted by permission of Wiley-Blackwell.

by steppe, grassland, and semiarid woodland in more continental areas. These ecosystems, which experience deep seasonal frost, represent the outer spatial extent of periglacial environments.

Periglacial Landscapes

Periglacial landscapes range between those in which the entire landscape is fashioned by permafrost and frost action processes and those in which frost action processes are subservient to others. This diversity is accentuated by the fact that (a) certain rock types are more prone

to frost action than others, (b) many regions currently experiencing periglacial climatic conditions have only recently emerged from beneath continental ice sheets and are largely glacial landscapes, and (c) the Pleistocene periglacial conditions fluctuated considerably in duration, extent, and intensity. Thus, many so-called periglacial landscapes are more accurately described as being *paraglacial* (i.e., in transition from glacial to nonglacial conditions), while the icefree areas of the Antarctic continent, being peripheral to the vast East and West Antarctic ice domes, are essentially *proglacial* in nature.

Typical lowland tundra terrain on the southern side of Banks Island, Arctic Canada. Fluvial terraces, thaw lakes, and tundra polygons are characteristic. Note the musk oxen grazing on the tundra and the soil instability on the sloping terrain in the immediate foreground.

Source: Author.

Geomorphic processes clearly unique to periglacial environments include (a) the formation of permafrost and ground-ice bodies, (b) the thermal-contraction cracking of frozen ground, (c) the thawing of permafrost (thermokarst), and (d) the creep of ice-rich permafrost. The most dramatic periglacial landform is the *pingo*, a conical ice-cored mound (see pingos photo). Equally dramatic are ground-ice slumps that occur locally wherever massive icy bodies are exposed within the permafrost. The most common feature of lowland permafrost terrain is large polygonal networks of thermal-contraction cracks. Typically, they are 15 to 30 m in dimension (see tundra polygons photo). The cracks are filled either with ice, forming tapered bodies of foliated ice known as ice wedges, or by a combination of ice and wind-blown material to form sand or composite

wedges. Thermally induced lateral movement in the near-surface layer transports material from the center of the polygon toward the periphery to form shallow ridges on either side of the thermal-contraction crack. The result is the formation of low-centered polygons. The transition to high-centered polygons usually reflects better drainage. In bedrock, thermal-contraction cracking often occurs along joints and other lines of weakness. The thaw erosion of ice-rich permafrost often leads to gulying along the ice wedges and the growth of thaw lakes and ponds. The creep of ice-rich permafrost is slow, measured in just millimeters per year, but in alpine environments, the movement of rock glaciers is more rapid.

Other processes, not necessarily restricted to periglacial environments, are important on account of their high magnitude or frequency.

The largest concentration of pingos, more than 1,350, occurs in the Mackenzie Delta region, Northwestern Arctic Canada. The majority occur in recently drained lake basins. Ibyuk Pingo, near Tuktoyaktuk, is one of the largest and best known.

Source: Author.

These center on the frost weathering of soils and surficial materials, leading to the formation of patterned ground and disturbed near-surface soil profiles and to the disintegration of exposed bedrock by frost wedging, growth of segregated ice lenses, or a complex of poorly understood physicochemical (cryogenic) and biological weathering processes. In uplands and areas of coherent bedrock, coarse, angular rock-rubble, termed *block-fields* or *kurums*, occurs widely. More resistant bedrock outcrops form cliffs, isolated hills, and tors. Frost widening of joints is also common. Wind action, in the form of abrasion and eolian sediment movement, is especially important in Antarctica and Northeast Greenland, where strong katabatic winds flow outward from the continental ice sheets, and elsewhere in the polar deserts, where the absence of vegetation allows for effective wind erosion. In the tundra lowlands, mass wasting of water-saturated near-surface materials follows the snowmelt in spring and

early summer. Commonly referred to as *solifluction*, this leads to gentle, undulating relief. Frost heaving and ice segregation in the near-surface thawed zone (the active layer) commonly result in small-scale sorted and nonsorted patterned ground (circles, stripes, and lobes), frost heaving of bedrock, and the formation of hummocks microtopography (thufurs, earth hummocks).

Human Occupancy and Environmental Concerns

Periglacial environments are part of the cryosphere. As such, if global climate change proceeds as predicted, periglacial environments will be among the first to be affected. This is because periglacial environments act as a positive feedback mechanism for climate warming. It is now understood that the hydrological cycle of the big northern rivers of North America and Eurasia links snowmelt and precipitation with river runoff, sea

Tundra polygons, 15–25 m in dimension, are characteristic of permafrost terrain. On the northern slope of Alaska, buildings, roads, and other forms of economic infrastructure are constructed on gravel pads to minimize disturbance to the thermal regime of the tundra. This photo, taken in 1979, shows a recently abandoned exploratory well site.

Source: Author.

ice, and ocean circulation in a single system. This influences deepwater formation in the Arctic basin and the corresponding global thermohaline circulation of the oceans. At the same time, any reduction in the extent of sea ice or snow cover reduces the albedo, or reflectivity, of land or ocean surface and allows more solar radiation to be absorbed.

In North America, the thawing of discontinuous permafrost at the southern (warm) limits of the discontinuous permafrost zone has been ongoing for more than 50 years. This trend is continuing, and the tree line is slowly but progressively advancing northward. In many parts of the world, the active layer is beginning to increase in thickness. The latter, monitored by the Circumpolar Active Layer Monitoring (CALM) program of the International Permafrost Association, will lead to

an increase in slope instability, changing snow-melt and hydrological regimes, and enhanced mass wasting and landscape modification in permafrost environments. Increased thaw will also affect near-surface, organic-rich layers at the active layer/permafrost boundary, especially in the subarctic. This will release significant quantities of carbon dioxide and methane, both of which are important greenhouse gases. In the alpine midlatitude periglacial environments, thawing permafrost may lead to instability of rock outcrops, which may threaten the foundations of ski lifts and other recreational installations at high elevation. Such problems are of special concern in the mountain regions of Western Europe.

In recent years, several other geotechnical and environmental concerns have come to be

The Trans-Alaska Pipeline System carries warm oil from Northern Alaska to Valdez on the Pacific coast. Where the pipe traverses warm permafrost, as near Fairbanks, Central Alaska, the pipe is elevated on vertical support members that are equipped with cooling devices (“heat tubes”) to prevent heat transfer from the pipe to the thaw-sensitive permafrost beneath.

Source: Author.

associated with periglacial environments. Geotechnical problems are widespread and relate largely to the water and/or ice content of permafrost. For example, frost heave causes significant damage to building structures and foundations. For example, in the case of pile foundations for buildings, repeated cycles of heave can progressively lift the pile, causing the structure to become unstable. The annual cost of rectifying seasonal frost damage to roads, underground utilities, and buildings in areas of permafrost and deep seasonal frost, as currently exist in large parts of Northern Canada, Alaska, Sweden, Northern Japan, and Russia, is considerable. The thaw of frozen ground also presents problems. For example, in unconsolidated ice-rich sediments, thaw consolidation may occur as sediments compact and settle under their own weight, thereby generating

high pore-water pressures that favor slope instability and slumping. There is also a significant loss of bearing strength on thawing. Another group of problems relates to the unusual hydrological and groundwater characteristics of permafrost terrain. Permafrost prevents the infiltration of surface water; restricts groundwater movement to unfrozen zones, or *tàliks*; and may cause groundwater to be highly mineralized. The availability of good drinking water is a major problem for many small communities in the permafrost regions of North America and Siberia.

Modern construction techniques aim to maintain the thermal equilibrium of the permafrost and to avoid the onset of thermokarst. The most common technique is the use of a gravel pad placed on the ground beneath the structure (see polygon photo). This compensates for the increase

in thaw that results from the warmth of the structure. Another technique is to mount the structure on wooden or concrete piles, thereby creating an air space between the ground surface and the structure. This allows air circulation to dissipate the heat coming from the structure. More sophisticated techniques include insertion of open-ended culverts, the use of insulated matting, and, if the structure justifies it, the insertion of costly refrigeration devices (“cryo-anchors”). In regions of warm permafrost and where large engineering ventures are concerned, so-called passive cooling methods are increasingly being used. These maintain thermal equilibrium by taking advantage of seasonal convection in high-permeability rock debris and are especially appropriate for road, rail, and airport embankments. The same technique is used to maintain the frozen nature of hazardous containment dykes at oil storage facilities and earthen dams constructed to contain toxic mine tailings and other contaminants.

The construction of oil and gas pipelines through permafrost terrain poses special problems. With warm-oil pipelines, the problem is the potential thaw of permafrost and the rupture of the pipe. In the case of the Trans-Alaska Pipeline System, which was constructed in the mid 1970s, the pipe was elevated above the ground on vertical support members wherever ice-rich permafrost was present (see Trans-Alaska Pipeline System photo). In the case of chilled-gas pipelines, which are usually buried and operate best when the gas is chilled to temperatures below zero, the problem is one of prolonged frost heave adjacent to the pipe and the creation of a frost bulb around the pipe. Satisfactory engineering solutions are yet to be devised to overcome this problem.

Increased economic activity in periglacial regions has been associated with human-induced terrain damage. For example, the search for oil and gas in regions such as Northern Alaska in the late 1940s and early 1950s and the Yamal Peninsula in Western Siberia in the late 1980s resulted in significant human-induced thermokarst activity following indiscriminate vehicle movement over the tundra terrain in summer. Thaw erosion along vehicle tracks that destroys surface vegetation commonly takes several decades to stabilize. The containment of waste-drilling fluids at the sites of exploratory drillings and of oil spills and

leakages from producing wells poses additional problems. Land use and regulatory problems by governments and administrative bodies are increasing in complexity and number.

PERMACULTURE

Permaculture is an adaptive, integrated, and holistic design science providing a symbiotic relationship between modern and indigenous cultures specific to a permanent place within ecological systems. The word *permaculture* was first used in the mid 1970s by Bill Mollison, an Australian ecologist, and his student David Holmgren. It involves a synergism of permanent agriculture evolving to a permanent culture. Permaculture designs patterns of ecosystems that balance human habitats with self-sufficient community food production systems. The ecological design path aims to preserve biodiversity through closed natural ecosystems. The scientific principles of permaculture lie generally within the synthesis of systems ecology and geography. The land use systems principles promote a resilient ecosystem and society.

Permaculture merges traditional cultures with local organic agriculture in urban and rural land design. The design is site specific with respect to locally adapted agrarian production techniques. It uses built environment green-building techniques such as solar and wind power, greenhouses, energy-efficient housing, and solar food cooking and drying. Permaculture integrates agroecological methods of production, using standard organic farming and gardening techniques, including cover crops, green manures, crop rotation, and mulches.

Permaculture Ethics

The ethics of permaculture provide a broad sense of three principles common to most indigenous tribal cultures. These cultures have existed in balance with their environment in a rooted community for many generations.

1. *Care of the Earth*: caring for the Earth from the soil up through a spiritual connection with all living and nonliving things in one's basic everyday decisions. The pragmatic philosophy of permaculture acknowledges the ecological limits of the Earth.
2. *Care for people*: promotes self-reliance and an interconnected web of community responsibility, reducing one's own dependence on the global economy and replacing it with local resources. Permaculture designs landscapes in which biodiversity and its members thrive in the bioregion.
3. *Setting limits to consumption and reproduction and redistributing surplus*: a sense of limits evolves from the knowledge that everything in nature has a limited lifespan and place. Monitoring one's own ecological footprint is a method to determine one's own individual needs within the capacity of the Earth. Redistributing one's local surplus of knowledge of permaculture skills or resources such as water, energy, or food helps build local community webs outside one's own bioregion.

Principles

Permaculture principles promote community change to improve global external environmental conditions. According to David Holmgren, there are 12 conceptual permaculture design principles:

1. Observe and interact.
2. Catch and store energy.
3. Obtain a yield.
4. Apply self-regulation and accept feedback.
5. Use and value renewable resources and services.
6. Produce no waste.

7. Design from patterns to details.
8. Integrate rather than segregate.
9. Use small and slow solutions.
10. Use and value diversity.
11. Use edges and value the marginal.
12. Creatively use and respond to change.
